Abstract. Wastewater contains stable and unstable pollutants. In the process of self-cleaning, a large amount of bottom sediments accumulates, especially in artificially created storage ponds. As a result of the increasing load on this type of water bodies and the accumulation of bottom sediments, the self-purification ability is sharply reduced, which entails an additional load on the environment. The use of bottom sediments for biological reclamation is allowed after the establishment of the hazard class in accordance with the current regulatory documents and taking measures to neutralize them. The purpose of this separate fragment of work was to study the total content of heavy metals in the bottom sediments of storage ponds of a milk processing enterprise and determine the possibility of their further use. As a result of the data obtained, it can be concluded that the lead content was 14.6-17.3 mg/kg, depending on the depth of the bottom sediment sampling layer. At a sampling depth of 0.5-1.0 meters, the lead content was maximum and exceeded the clarke values of the element by 8.1%. There is a 2-time excess of the clarke values for cadmium at a depth of 1.0-1.5 meters. Indicators for zinc and copper were 12.4-14.1 mg/kg and 5.9-9.8 mg/kg, respectively, and did not go beyond the threshold limits of the compared values. The research results allow concluding that the bottom sediments of the storage ponds of the milk processing enterprise are not toxic. Therefore, they can be used in the composition of soil.

1 Introduction

The resistance of ecosystems to anthropogenic impacts depends on their self-purification ability. The contribution of individual processes to the self-purification of water depends on the nature of pollutants, temperature, species composition of microbiocenosis and hydrochemical parameters [1, 2].

Food industry enterprises are one of the most resource-intensive ones in agribusiness, whose activities are accompanied by a high consumption of energy and water resources per unit of production, and a significant amount of polluted wastewater is generated, which have a negative impact on the environment. Along with this, they have great potential for
introducing the best available technologies and increasing the efficiency of using natural resources [3, 4].

Wastewater from food processing plants contains stable and unstable contaminants. In most cases, the nature and concentration of substances do not change over time [5]. The concentration of some naturally stable substances may decrease due to their volatility, reaction with other substances, or due to biochemical processes (destruction of organic substances) [6-8]. As a result of the total influence of these processes, there is a decrease in the concentration of the incoming substances in the reservoir until complete disappearance of some of them, or, in other words, self-purification. In the process of self-purification, a large amount of bottom sediments accumulates, especially in artificially created storage ponds. As a result of the increasing load on this type of water bodies and the accumulation of bottom sediments, the self-purification ability sharply decreases [9, 10]. Therefore, it becomes necessary to look for possible ways of using the sediment, but this is complicated by the fact that it can also contain a large amount of non-degradable pollutants.

The use of bottom sediments for biological reclamation is allowed after the establishment of the hazard class in accordance with the current regulatory documents and taking measures to neutralize them [11, 12].

The purpose of this separate fragment of the work was to study the total content of heavy metals in the bottom sediments of storage ponds of the milk processing enterprise and determine the possibility of their further use.

2 Materials and Methods

The object of the study was the bottom sediments of the storage ponds of the milk processing enterprise.

Based on the Guidelines for the implementation of state monitoring of water bodies [13, 14] in terms of organizing and conducting observations of the content of pollutants in bottom sediments of water bodies, Order No. 112 dated 24.02.2014, for a general description of the characteristics of bottom sediments, their visual and physical characteristics, temperature, and pH values were determined. Also, samples were taken for laboratory research.

To determine the hazard rate of bottom sediments in accordance with section II of the Order of the Ministry of Natural Resources of Russia dated December 4, 2014 №536 “On approval of the criteria for classifying waste to I-V hazard classes according to the degree of negative environmental impact”, samples of bottom sediments were taken. Samples of soil, subsoil and bottom sediments were taken (Fig. 1) in accordance with the Russian State Standard GOST 12071-2014 by the point method using a soil sampler every 0.5 m during vertical drilling at 3 control points (Fig. 1) and placed in sealed bags (Fig. 2).
introducing the best available technologies and increasing the efficiency of using natural resources [3, 4].

3 Results/Discussion

The use of bottom sediments for biological reclamation or other purposes is allowed after the hazard class is established in accordance with the current regulatory documents and measures are taken to neutralize them.

The content of heavy metals in bottom sediments is one of the most objective and reliable indicators of pollution of aquatic systems [15, 16].

The obtained data on the content of heavy metals in the bottom sediments of storage ponds presented in Table 1 were compared with the clarke value and freshwater bottom sediments.
Table 1. Content of heavy metals in bottom sediments, mg/kg.

| Chemical element | Content in bottom sediments | Clarke of the lithosphere * | Freshwater BS** |
|------------------|----------------------------|----------------------------|-----------------|
|                  | 1  | 2  | 3  | 1  | 2  |
| Lead             | 14.6 | 17.3 | 15.2 | 16 | 28 |
| Cadmium          | 0.03 | 0.03 | 0.26 | 0.13 | 0.35 |
| Zinc             | 14.1 | 13.6 | 12.4 | 83 | 110 |
| Copper           | 7.8  | 9.8  | 5.9  | 47 | 43 |

Note * - clarkes of the lithosphere (A.P. Vinogradov, 1987), ** - freshwater bottom sediments (U. Forstner 1977).

As a result of the data obtained, it can be concluded that the content of lead was 14.6-17.3 mg/kg, depending on the depth of the layer of bottom sediments selection. At a sampling depth of 0.5-1.0 meters, the lead content was maximum and exceeded the element's clarkes values by 8.1%. There is a 2 time excess of the clarkes values for cadmium at a depth of 1.0-1.5 meters. Indicators for zinc and copper were 12.4-14.1 mg/kg and 5.9-9.8 mg/kg, respectively, and did not go beyond the threshold limits of the compared values.

According to the concentration of heavy metals, precipitation for agricultural use is divided into two groups. Sediments with a higher concentration of heavy metals, but at the same time corresponding to IV-V classes of environmental hazard, are allowed for use in technical reclamation.

The gross content of heavy metals at a depth of up to 1.5 meters is presented in Table 2.

Table 2. Gross content of heavy metals (mg/kg).

| Indicator | Samples | Concentration of dry matter, mg/kg, no more, for group of sediments |
|-----------|---------|---------------------------------------------------------------------|
|           | background site | experimental site | I | II |
| Pb        | soil     | soil and subsoil | subsoil | bottom sediments | 1  | 2  | 3  | 1  | 2  |
|           | 16.3     | 16.4           | 17.1   | 14.6 | 17.3 | 15.2 | 250 | 500 |
| Cd        | 0.03     | 0.03           | 0.25   | 0.03 | 0.03 | 0.26 | 15  | 30  |
| Zn        | 24.7     | 21.7           | 16.3   | 14.1 | 13.6 | 12.4 | 1750| 3500|
| Cu        | 10.3     | 8.1            | 9.7    | 7.8  | 9.8  | 5.9  | 750 | 1500|

The table shows that in the samples under study, none of the elements exceeds the permissible bulk content of heavy metals. It is much lower for all elements than the criteria of the first group. This is important to note, since if the content of at least one of the standardized elements exceeds its permissible level for group I, then sediments is attributed to group II.

Sediments of groups I and II are used in industrial floriculture, green construction, forest and ornamental nurseries, for biological reclamation of disturbed lands and landfills of municipal solid waste (GOST 17.4.3.07-2001).

4 Conclusion

The research results allow concluding that bottom sediments of storage ponds are not toxic. Therefore, they can be used in the composition of soil and subsoil. In the case of non-agricultural use of bottom sediments, the application rates should be determined by crop cultivation technologies and areas of reclamation (GOST R 54534-2011). General requirements for the use of sediments for reclamation of disturbed lands are determined by GOST 17.5.3.04.

The procedure for using bottom and silt sediments as a component of plant soil is determined by the technological regulations, which are developed by specialized
organizations taking into account regional and local conditions, including soil properties and hydrological regime, the content of normalized pollution in sediments and soil, total and mineral nitrogen, phosphorus, potassium, and peculiarities of crop cultivation.
