ABSTRACT

A facile one-pot synthesis method has been developed successfully for the preparation of crystalline silver selenide (Ag$_2$Se) nanoparticles at low temperatures (5–7 °C) within few minutes. The method is based on the formation of phase separation and interface-reaction mechanism. During the synthesis, a microemulsion system (water/oleic acid/n-hexane) was used to make Ag$_2$Se nanoparticles. Selenium source (Sodium selenosulfate) used in this synthesis method was prepared by microwave heating due to the fact that the developed method of synthesis could eliminate toxic and expensive selenium sources. The prepared products (oleic acid coated Ag$_2$Se nanoparticles) were characterized by X-ray diffraction (XRD), energy-dispersive X-ray analysis (EDX), transmission electron microscopy (TEM), ultraviolet (UV)–visible analysis and photoluminescence (PL) analysis. The developed method became mild, fast, simple and environmentally benign, which would be helpful in scaling up production. Furthermore, the developed synthesis strategy could be used in making other nanoparticles for mass production through simple precipitation reactions.

Precipitation reaction

1. Introduction

In past decades, silver selenide (Ag$_2$Se) has received great attention due to its special electronic and optical properties as well as potential applications [1–3]. Ag$_2$Se undergoes a polymorphic phase transition and has two stable solid phases. These are a low temperature orthorhombic phase (β-Ag$_2$Se) at 0 K, and a high temperature cubic phase (α-Ag$_2$Se) with a phase transition temperature from β to α-Ag$_2$Se taking place at about 135 °C or 409 K [2,4,5]. The low-temperature phase behaves as a semiconductor, while the high-temperature shows the properties of a metal. A low temperature phase (β-Ag$_2$Se) is a narrow band gap and n-type semiconductor with an energy gap of 0.07 eV at 0 K [5]. β-Ag$_2$Se is used as a photo sensitizor in photographic films or in thermo chromic materials and thermo electronic application due to its relatively high see back coefficient, low lattice thermal conductivity, and a high electrical conductivity [3,4,6–9]. The high-temperature phase (body-centered cubic), α-Ag$_2$Se, is a metallic compound with super ionic conductors that has been utilized as a solid electrolyte in photochargeable secondary batteries and also used as an additive in highly conductive composite glasses for batteries, sensors, and displays [3,4,6–9].
Recently, research reports indicated that a slight tuning of the stoichiometry to Ag$_2$Se could induce a remarkable magneto resistance, which is comparable to the giant magneto resistance perovskites [10–12]. Since nanoscale materials have some unique properties (that depend on the size and morphology of the particles) for a unique application [13,14], it would be a great challenge to fabricate Ag$_2$Se nanostructures having uniform size and morphology. A number of methods for the synthesis of Ag$_2$Se nanostructures have been explored [3,4,8,15,16]. All these routes to Ag$_2$Se nanostructures, however, did not satisfy the criteria that the method be simple and fast, i.e., Ag$_2$Se forms at low temperature in one step, and the prepared samples had nearly uniform morphology. Most of these Ag$_2$Se synthesis routes have also used expensive and toxic selenium sources.

In this report, we employed a single step (the one pot) synthesis strategy to prepare uniform-sized Ag$_2$Se nanoparticles at low temperature by reacting Ag with SeSO$_3$ under mild condition. In such synthesis approach, Na$_2$SeSO$_3$ was used as a selenium source since it could easily react with Ag$^+$ ions at room temperature without requiring the use of any other forms of energy [17]. Na$_2$SeSO$_3$ is much more active than Se powder, and is also less toxic, inexpensive and therefore safer to use than the Na$_2$Se or H$_2$Se [18]. Na$_2$SeSO$_3$ was prepared via microwave-enhanced method. A microwave-enhanced method, as opposed to conventional heating, has been proven to be an excellent technique for preparation of nanoparticles [18]. A few of the advantages of microwave-enhanced reactions include: simple to control the properties of the products, high yields of products, easy to control the temperature and pressure profile, the products have high purity levels, short reaction time, and environmental friendliness (e.g., improved safety, reproducibility, and selective heating, energy savings, etc.) [18]. A low-temperature microemulsion [19,20] environment was introduced to protect the prepared Ag$_2$Se nanoparticles from aggregation and to direct them into a relatively uniform size. The low temperature reaction conditions also helped the formation of nearly monodisperse Ag$_2$Se nanoparticles by slowing the growth speed and decreasing the surface atom activity.

The structure, morphology, elemental composition, and optical properties of the prepared Ag$_2$Se nanoparticles were characterized by XRD, TEM, EDX, and UV–vis and Fluorescence spectrophotometer respectively. The developed synthesis method used very simple reagents such as oleic acid, AgNO$_3$, and Na$_2$SeSO$_3$ as precursors; was fast, easy/simple, mild, environmentally benign and of low temperature, which would be useful for large scale production and could be applied for the synthesis of other similar nanostructure materials.

2. Experimental section

2.1. Chemicals

Selenium powder (Se, 99.70%, <325 mesh), sodium sulfite (Na$_2$SO$_3$, >95%), and n-hexane (>99%) were bought from Acros; ethanol (>99%) and oleic acid (65–88%) were brought from Aldrich; Silver nitrate (AgNO$_3$, >99%) and sodium hydroxide (NaOH, >95%) were bought from Shimakusy Pure Chemicals. The chemicals were used without further purification. The microwave system was employed for the synthesis of sodium selenosulfate (Na$_2$SeSO$_3$).

2.2. Synthesis of sodium selenosulfate (Na$_2$SeSO$_3$)

It was prepared in the laboratory using microwave-enhanced methods. The advantages of microwave heating over the conventional heating are explained above. Microwave (MW) synthesis was done by using a single-mode CEM Discover System operating at 300 W and 2.45 GHz. The reaction mixture was rapidly cooled with high-pressure air following termination of the reaction. Na$_2$SeSO$_3$ was prepared from sodium sulfite and selenium powder by microwave heating in aqueous solution for 30 min at 100 °C. For a typical preparation, selenium powder (0.4 g) and Na$_2$SO$_3$ (0.76 g) were dissolved in distilled water (50 mL); then, they were transferred to the microwave system. The following chemical reaction describes the formation of Na$_2$SeSO$_3$ under microwave system for 30 min reaction time at 100 °C.

$$\text{Na}_2\text{SO}_3 + \text{Se} \rightarrow \text{MW (100 °C and 30 min)} \rightarrow \text{Na}_2\text{SeSO}_3$$

Sodium selenosulfate (Na$_2$SeSO$_3$) was considered to be a greener selenium precursor than organic-based Se sources such as trioctylphosphine/Se or trioctylphosphine oxide/Se or others [18].

2.3. Synthesis of Ag$_2$Se nanoparticles

The synthesis of Ag$_2$Se nanoparticles was done in three steps. First step, NaOH (0.12 g) and oleic acid (2 mL) were dissolved in the mixture of deionized water (15 mL), C$_2$H$_5$OH (15 mL), and n-hexane (1.5 mL) to form a transparent microemulsion. Second, AgNO$_3$ (0.23 g) dissolved in deionized water (5 mL) was added to the solution (transparent microemulsion) under vigorous stirring, forming a white Ag$^+$ containing emulsion quickly. Third and the last step, after the emulsion had been maintained in the temperature range of 5–7 °C in the water bath, Na$_2$SeSO$_3$ solution (5 mL) was injected into it. The prepared solution changed its color from transparent to black in a few seconds, and stirring continued for up to 10 min.

After the reaction, n-hexane (20 mL) was added to destroy the microemulsion and extract the oleic acid-coated Ag$_2$Se nanoparticles into the oil phase, which was centrifuged to give Ag$_2$Se nanoparticles by adding C$_2$H$_5$OH. Then, the samples were washed more than three times by dissolving n-hexane coupled with precipitation from ethanol to remove oleic acid residues on the particle surface. Finally, the as prepared Ag$_2$Se nanoparticles were dispersed in n-hexane for storage. The following chemical reaction describes the formation of Ag$_2$Se nanoparticles with simple precipitation reactions.

$$\text{Na}_2\text{SeSO}_3 + 2\text{AgNO}_3 + \text{H}_2\text{O} \rightarrow \text{Ag}_2\text{Se(s)} + 2\text{NaNO}_3 + \text{H}_2\text{SO}_4$$

2.4. Characterization

Photoabsorption and photoluminescence measurements were performed by using a Jasco 560 UV/Vis Spectrophotometer and a Hitachi F-7000 Fluorescence spectrophotometer, respectively.
X-ray diffraction (XRD) measurements (Rigaku Model D\textsubscript{max}-B, Japan) were recorded using a Cu K\textalpha
eradiation source that was operated at 40 kV and 100 mA. The X-ray diffractogram was obtained at a scan rate of 0.05 deg s\(^{-1}\) for 2\(\theta\) values. The TEM images were obtained by using a Philips Tecnai 20 G2-field emission gun with a maximum acceleration voltage of 200 keV. The chemical composition of the Ag\textsubscript{2}Se nanoparticles was measured by energy-dispersive X-ray spectroscopy (EDX). FTIR spectra were recorded by using a Digilab FT3500 spectrometer (64 scans with a resolution of 4 cm\(^{-1}\)).

3. Results and discussion

Fig. 1 shows the XRD patterns of Ag\textsubscript{2}Se nanoparticles obtained at the reaction times of 10 min and particle-growth temperatures of 7 °C. As seen in Fig. 1, the as-prepared Ag\textsubscript{2}Se nanoparticles show characteristic peaks of orthorhombic phase of \(\beta\)-Ag\textsubscript{2}Se. All the characteristic peaks, seen in Fig. 1, correspond to the orthorhombic phase of \(\beta\)-Ag\textsubscript{2}Se, which is in good agreement with the literature data for \(\beta\)-Ag\textsubscript{2}Se (the standard JCPDS card File, 24–1041). As reported in literature \([16,21–26]\), it seems also logical to produce the orthorhombic phase at low temperature since it is a low-temperature stable phase. A slight peak broadening, shown in the XRD patterns, may reflect the smaller particle size (around 8 nm) of the products.

Fig. 2a and b shows the TEM images of the as-prepared products at different magnifications. The products are nearly monodisperse without any aggregation with the particle size ranges from 6 to 10 nm. The average particle size is calculated to be 8 nm. The high-resolution transmission electron microscopy (HRTEM) images in the inset of Fig. 2b show the lattice spacing of \(\sim\)0.24 nm, corresponding to the characteristic of the (013) crystal planes of \(\beta\)-Ag\textsubscript{2}Se nanoparticles \([27,28]\).

Fig. 3 shows the Energy Dispersive X-ray (EDX) spectrum taken from the selected area of SEM images (seen in the inset figure in Fig. 3). The result of the EDX shows that the atomic ratio of the Ag and Se in this tubular product is 66.33:33.67, close to the stoichiometric composition of the Ag\textsubscript{2}Se. Thus, the atomic composition of Ag and Se, in the as-prepared products, is merely similar to the stoichiometric composition of Ag\textsubscript{2}Se.

Fig. 4 shows the FTIR spectra of the as-prepared Ag\textsubscript{2}Se nanoparticles and the pure oleic acid (OA). FTIR spectroscopy can offer insight about the interaction between the oleic acid and the Ag\textsubscript{2}Se nanoparticles. The broad peak between 3500 and 2500 cm\(^{-1}\) was observed in the pure oleic acid spectra, which is clearly due to the O—H stretch of the carboxylic acid \([29–33]\). Such a broad and intense band at high wave number is a typical characteristic of O—H functional group of the carboxylic acid. However, the as-prepared Ag\textsubscript{2}Se nanoparticles have no such bands in this region indicating that the oxygen atoms in O—H groups were chemisorbed on the surface of Ag\textsubscript{2}Se nanoparticles.

A pure oleic acid spectra show two sharp bands at 2925 and 2857 cm\(^{-1}\), which were superimposed on the O—H stretch, and were attributed to the asymmetric CH\textsubscript{2} stretch and the symmetric CH\textsubscript{2} stretch of the free OA, respectively \([29–31,34]\). When oleic acids were chemisorbed on the surface of Ag\textsubscript{2}Se nanoparticles, the asymmetric CH\textsubscript{2} stretch and the symmetric...
In the pure oleic acid spectra, the intense peak at 1710 cm\(^{-1}\) was due to the presence of the C\(=\)O stretch, and the band at 1285 cm\(^{-1}\) that indicated the presence of the C—O stretch \([29–31]\). In addition, the O—H in-plane and out-of-plane bands of the pure oleic acid appeared at 1463 and 934 cm\(^{-1}\), respectively \([29–31]\). These bands disappeared in Ag\(_2\)Se nanoparticles shown in Fig. 4, instead, two new bands at 1550 and 1440 cm\(^{-1}\) appeared, which are characteristic of the asymmetric \(v\)\(_{as}\)(COO\(^{−}\)) and the symmetric \(v\)\(_{s}\)(COO\(^{−}\)) stretching \([29–31]\), respectively. The results from FTIR spectra in Fig. 4 reveal that oleic acid was chemisorbed, as a carboxylate ion, onto the surface of the as-prepared Ag\(_2\)Se nanoparticles \(\text{o} \text{leic acid capped Ag}_2\text{Se nanoparticles or OA-capped Ag}_2\text{Se}\), and that the two oxygen atoms in the carboxylate were coordinated symmetrically to both the Ag and the Se atoms.

Based on the aforementioned experimental results, it seems possible to explain the role of oleic acid in such synthesis strategy of Ag\(_2\)Se nanoparticles. First, oleic acid and silver nitrate essentially lead to the formation of a silver oleate intermediate by replacing the nitrate group in the starting materials. Second, Se\(^{2–}\) is generated by the reaction of SeSO\(_3^{2–}\) with OH\(^{−}\). Third, the intermediate silver oleate reacts with Se\(^{2–}\) to form Ag\(_2\)Se nanoparticles surrounded by oleate groups. This method protects the nucleation of the tiny particles, as shown in the following schematic diagram below (Scheme 1).

In general, capping ligands could prevent the aggregation of small crystals and influence the morphology of the as-prepared nanoparticles. The dynamics of the surface ligands attached and detached could be varied by controlling the temperature and the nature of the ligand. Thus, the reaction temperature could be used to control the growth of nanocrystals.

To further confirm the formation of Ag\(_2\)Se nanoparticles and understand its optical properties, UV–visible absorption and photoluminescence (PL) measurement of the as-prepared Ag\(_2\)Se nanoparticles in n-hexane were performed. Fig. 5 shows the UV–visible absorption: (a) photoluminescence; (b) spectra of oleic acid capped Ag\(_2\)Se nanoparticles.

As seen from Fig. 5a, the absorption edge was determined at around \(λ = 635\) nm, which is close to the literature value \(λ = 629\) nm \([21]\) reported for Ag\(_2\)Se nanocrystals \([21,35]\). According to the relationship of the band gap energy \(E\)\(_g\) with the absorption edge, the \(E\)\(_g\) of the as-prepared Ag\(_2\)Se nanoparticles was calculated as 1.95 eV, and this value agrees well with the value reported \([21,35]\).

Fig. 5b shows the photoluminescence (PL) spectra of oleic acid capped Ag\(_2\)Se nanoparticles in n-hexane, with the

**Scheme 1** – The role of oleic acid in the formation of Ag\(_2\)Se nanoparticles at low temperature.
maximum PL intensity observed at around $\lambda_{\text{max}} = 510$ nm that may result from the direct interband radiative recombination [1].

4. Conclusions

In this work, a low-temperature, facile and fast synthesis strategy for nearly monodisperse orthorhombic phase Ag$_2$Se nanoparticles was developed. The optical properties, structure, morphology and other properties of the as-prepared samples were characterized by different instruments such as TEM, FTIR, UV–visible, PL, EDX and XRD. The characterization results of this instrument supported the formation of oleic acid capped orthorhombic phase $\beta$-Ag$_2$Se nanoparticles.

In general, to prepare uniform nanoparticles, the developed synthesis strategy has a number of advantages. Firstly, the synthesis of nanoparticles is completed at lower temperature in one-pot makes the system easy to control and manipulate. Secondly, it is a fast method of synthesis to prepare nanoparticles, and this makes the system economical. Thirdly, it is an ideal and general synthesis strategy in making other uniform nanoparticles for mass production through simple precipitation reactions. Last, but not least, this low temperature synthesis protocol is suitable for application in many other materials such as sulfides, fluorides, phosphates and so on, provided that high crystallinity is not required.
