We study the influence of a magnetic impurity or ultrasmall quantum dot on the charge persistent current of a mesoscopic ring. The system consists of electrons in a one-dimensional ring threaded by spin-dependent Aharonov-Bohm/Casher fluxes, coupled via an antiferromagnetic exchange interaction to a localized electron. By passing to a basis of electron states with definite parities, the problem is mapped onto a Kondo model for the even-parity channel plus free electrons in the odd-parity channel. The twisted boundary conditions representing the fluxes couple states of opposite parity unless the twist angles satisfy \( \phi_\alpha = f_\alpha \pi \), where \( f_\alpha \) are integers, with spin index \( \alpha = \uparrow, \downarrow \). For these special values of \( \phi_\alpha \), the model is solved exactly by a Bethe ansatz. Special cases are investigated in detail. In particular we show that the charge stiffness in the case \( \phi_\uparrow = \phi_\downarrow \) is insensitive to the presence of the magnetic impurity/quantum dot.

I. INTRODUCTION

Recent experimental breakthroughs in identifying a Kondo effect in a quantum dot connected to leads have led to a flurry of activities in mesoscopic Kondo physics. In a parallel development, data on Kondo scattering from a single magnetic impurity has also been reported. With Kondo physics now available in the laboratory at the mesoscopic scale, the full richness of this paradigm of many-body physics can be explored.

One of the basic fingerprints of coherent electron transport is that of the Aharonov-Bohm (AB) effect, which has already been observed in microstructured conducting rings coupled to a quantum dot. A natural question to ask is how the AB effect and its dual, the Aharonov-Casher (AC) effect, in a ring coupled to a quantum dot and hence e.g. the persistent currents would be modified by the many-body correlations present in the Kondo regime.

As is well-known, charge and spin persistent currents are the equilibrium responses of a multiply-connected system to a magnetic AB flux and/or an AC flux of a charged string (ABC fluxes) piercing the system. The persistent current of a ring coupled via tunneling to a quantum dot was investigated via perturbation theory and numerical diagonalization by Büttiker and Stafford. In this article, we study a variant of the problem where electrons in a one-dimensional (1D) ring threaded by spin-dependent ABC fluxes \( \phi_\alpha \) (\( \alpha = \uparrow, \downarrow \)) are coupled via antiferromagnetic exchange to a localized electron, representing a magnetic impurity or quantum dot. A detailed analysis shows that this model can be mapped onto the integrable Kondo model for special values of \( \phi_\alpha \), corresponding to periodic and antiperiodic boundary conditions. The model is solved via Bethe ansatz for these special values of \( \phi_\alpha \), and it is shown that the charge stiffness for \( \phi_\uparrow = \phi_\downarrow \) is insensitive to the Kondo scattering, implying that spin-charge separation holds even on the mesoscopic scale in this model. However, for \( \phi_\uparrow \neq \phi_\downarrow \) the charge persistent current is affected by the presence of the magnetic impurity, as can be shown by a detailed analysis of the Bethe ansatz equations.

II. EXACTLY SOLVABLE MODEL

The system we are considering is described in the continuum limit by the 1D Hamiltonian,

\[
H = -\frac{\hbar^2}{2m} \sum_\alpha \int_0^L dx \left( \psi_\alpha^\dagger(x) \frac{\partial^2}{\partial x^2} \psi_\alpha(x) + \lambda \sum_{\alpha,\beta} \psi_\alpha^\dagger(0) \hat{\sigma}_{\alpha\beta} \psi_\beta(0) \cdot \vec{S} \right),
\]

where...
where $\lambda > 0$ is an antiferromagnetic Kondo coupling, $m$ is the electron mass, $L$ is the circumference of the ring, $\vec{S}$ is the impurity spin (located at $x = 0$), and $\psi_\alpha$ is an electron field with spin index $\alpha = \uparrow, \downarrow$. The effect of the fluxes $\phi_\alpha$ has been gauged away and encoded in twisted boundary conditions:

$$\psi_\alpha(L) = e^{i\phi_\alpha} \psi_\alpha(0),$$

(2)

where $\phi_{\uparrow, \downarrow} = 2\pi(\Phi/\Phi_0 \pm 4\pi\tau/F_0)$. Here $\Phi$ is the magnetic flux enclosed by the ring and $\tau$ the line charge density of a charged string passing through the center of the ring. $\Phi_0 = hc/e$ is the elementary magnetic flux quantum, with $F_0 = hc/\mu$ its electric analogue, $\mu$ being the projection of the magnetic moment along the string.

We are interested in an exact solution of the problem described by (1) and (2), with a particular eye on how the Kondo interaction in (1) may affect the persistent current induced by the boundary phase angles $\phi_\alpha$ describing the ABC fluxes. Since the essential physics of the system is confined to a small region around the left and right Fermi points, we can linearize the quadratic dispersion in (1) around $\pm k_F$ and introduce left ($l$) and right ($r$) moving chiral fields:

$$\psi_\alpha(x) \sim e^{-ik_F x} \psi_{l,\alpha}(x) + e^{ik_F x} \psi_{r,\alpha}(x).$$

(3)

The Hamiltonian then becomes:

$$H = H_0 + H_{\text{imp}},$$

(4)

with

$$H_0 = \frac{v_F}{2\pi} \sum_\alpha \int_0^L dx \left( \psi_{l,\alpha}^\dagger(x) i\partial_x \psi_{l,\alpha}(x) - \psi_{r,\alpha}^\dagger(x) i\partial_x \psi_{r,\alpha}(x) \right),$$

(5)

and

$$H_{\text{imp}} = \lambda \sum_{\alpha, \beta} \left( \psi_{l,\alpha}^\dagger(0) + \psi_{r,\alpha}^\dagger(0) \right) \vec{\sigma}_{\alpha\beta} \left( \psi_{l,\beta}(0) + \psi_{r,\beta}(0) \right) \cdot \vec{S}.$$ 

(6)

To make progress, it is convenient to pass to a basis of definite parity fields (Weyl basis):

$$\psi_{\text{even},\alpha}(x) = \frac{1}{\sqrt{2}} (\psi_{l,\alpha}(x) + \psi_{r,\alpha}(-x)),$$

(7)

an even–parity, right–moving electron field, and

$$\psi_{\text{odd},\alpha}(x) = \frac{1}{\sqrt{2}} (\psi_{r,\alpha}(-x) - \psi_{l,\alpha}(x)),$$

(8)

an odd–parity, left–moving field. One should note that the assignment of chirality (left/right) to parity (odd/even) is not intrinsic, but a property of the particular transformations (7) and (8). This is analogous to a gauge–fixing condition. In this basis the Hamiltonian takes the form:

$$H = H_0^{\text{odd}} + H_0^{\text{even}} + H_{\text{imp}}^{\text{even}},$$

(9)

where

$$H_0^{\text{even}} = -\frac{v_F}{2\pi} \sum_\alpha \int_0^L dx \psi_{\text{even},\alpha}^\dagger(x) i\partial_x \psi_{\text{even},\alpha}(x),$$

(10)

and

$$H_0^{\text{odd}} = \frac{v_F}{2\pi} \sum_\alpha \int_0^L dx \psi_{\text{odd},\alpha}^\dagger(x) i\partial_x \psi_{\text{odd},\alpha}(x),$$

(11)

describe independent relativistic electrons, and the impurity contribution is now also diagonal:

$$H_{\text{imp}}^{\text{even}} = \lambda \sum_{\alpha, \beta} \psi_{\text{even},\alpha}^\dagger(0) \vec{\sigma}_{\alpha\beta} \psi_{\text{even},\beta}(0) \cdot \vec{S}.$$ 

(12)
We recognize $H^{\text{even}}_{\text{Kondo}} = H^{\text{even}}_{\text{imp}} + H_{\text{imp}}^{\text{even}}$ as the chiral Hamiltonian of the spin-$S$ Kondo model.

While the even and odd parity channels are decoupled in the Hamiltonian, they become connected by the twisted boundary conditions (3):

$$
\begin{pmatrix}
    \psi_{\text{even},\alpha}(L) \\
    \psi_{\text{odd},\alpha}(L)
\end{pmatrix} =
\begin{pmatrix}
    \cos \phi_\alpha & i \sin \phi_\alpha \\
    -i \sin \phi_\alpha & \cos \phi_\alpha
\end{pmatrix}
\begin{pmatrix}
    \psi_{\text{even},\alpha}(0) \\
    \psi_{\text{odd},\alpha}(0)
\end{pmatrix},
$$

(13)

where in (3) we have taken $k_F = (2\pi/L)n$, with $n$ an integer. However, for the special values $\phi_\alpha = f_\alpha \pi$, where $f_\alpha$ is an integer, the matrix in Eq. (13) reduces to a multiple of the unit matrix, and the even and odd parity states decouple from each other entirely. One can then solve $H^{\text{even}}_{\text{Kondo}}$ by the Bethe ansatz. Thus, our original problem in (3) and (4) has collapsed to an exactly solvable problem for $f_\alpha \in Z$, consisting of a left-moving odd-parity branch of independent relativistic electrons, together with a (decoupled) right-moving even-parity branch defined by the 1D Kondo model. For generic values of $\phi_\alpha$, it is not possible to choose a basis which renders the Hamiltonian and the boundary conditions simultaneously diagonal, suggesting that the model is not integrable in general. This is in apparent contradiction to recent claims in the literature about the integrability of the related Anderson ring threaded by an Aharonov-Bohm flux of arbitrary strength.

From Eq. (13), the impurity is seen to couple only to the spin current of the electrons, suggesting, via the dynamic spin-charge separation in 1D, that the charge persistent current is insensitive to the presence of the impurity. Although this indeed turns out to be the case—as we shall confirm via a Bethe ansatz analysis—some caveats are appropriate at this point: First, the persistent current is a boundary effect and, as such, could be influenced by non-dynamical selection rules for combining charge and spin. Secondly, and possibly reflecting this, a magnetic impurity does affect the charge current of a chiral ring of free electrons (with all electrons moving in the same direction). In any event, it is instructive to study the exact mechanism by which the charge persistent current in the present problem avoids any influence from the impurity. Moreover, the above is only true - as our exact Bethe ansatz solution shows - for $\phi_\uparrow = \phi_\downarrow$. In general, there is a marked effect of the presence of the magnetic impurity on the charge persistent current.

To carry out this analysis, we first need to consider how to properly define a persistent current for relativistic electrons, i.e. for electrons with a linear dispersion.

### III. Charge Persistent Current for Relativistic Electrons

In the usual treatment of independent 1D electrons, the persistent current is obtained by summing the partial currents $I_n = -(e/\hbar)\partial E_n/\partial \phi$ over all occupied levels $n$. This approach clearly fails for relativistic electrons since the corresponding linear dispersions

$$
E_{n_r} = \hbar v_F \frac{2\pi n_r + \phi}{L}, \quad n_r = 0, 1, 2, ..., n_F
$$

(14)

and

$$
E_{n_l} = \hbar v_F \frac{-2\pi n_l + \phi}{L}, \quad n_l = 1, 2, ..., n_F
$$

(15)

imply that $\partial E_n/\partial \phi =$ const. for all levels $n$. (Here, for simplicity, we consider a system of spinless electrons in which the total number of electrons $2n_F + 1$ is odd, with $l$ ($r$) denoting, as before, a branch of left (right) moving electrons.) To recover the known results for the persistent current, we must thus use a different approach. Let us introduce flux-dependent particle numbers

$$
N_{r/l}(\phi) = \frac{L}{2\pi} |k_{r/l,F}(\phi)| - |k_{r/l,F}(0)|,
$$

(16)

where $k_{r/l,F}$ are flux-dependent Fermi momenta, associated with the highest occupied level on the respective branch. The Fermi momenta $k_{r,F}$ and $k_{l,F}$ are cutoff dependent, and need not be equal. However, provided the cutoffs are chosen independent of $\phi$, $N_{r/l}(\phi)$ are insensitive to the cutoffs, and describe the physical response of the system to an ABC flux. The persistent current is then

$$
I(\phi) = -\frac{e v_F}{L} [N_r(\phi) - N_l(\phi)].
$$

(17)
It should be pointed out that the charge velocity $v_F$ is in general subject to renormalization due to electron-electron interactions.

With the choice of representative levels in (14) and (15) (note in particular that the zero mode is assigned to one branch only) it is easy to verify that (16) and (17) exactly reproduce the known result for the persistent current of an odd number of spinless 1D electrons. \[14\] Our construction, introduced here ad hoc, can trivially be extended to spinful particles and put on a firm basis by a proper analysis of the cutoff procedure for 1D relativistic electrons in the presence of ABC fluxes. \[14\] In short, a flux-dependent particle number as in (16) is the trade-off that guarantees that physical observables remain independent of the choice of cut off which bounds the spectrum of a finite system from below.

Given (17), the problem is now reduced to calculating how the effective particle numbers depend on the flux and the coupling of the electrons to the magnetic impurity. For this, we turn to a finite-size Bethe ansatz analysis.

**IV. FINITE–SIZE BETHE ANSATZ**

To obtain the flux dependent particle numbers for a finite ring, we apply the techniques of the Bethe ansatz for finite systems, developed previously for the 1D Hubbard model. \[17\] As pointed out above, our model is only integrable for $\phi_{\alpha} = f_{\alpha}\pi$, with $f_{\alpha}$ an integer. For $f_{\alpha} \in \mathbb{Z}$, the nested Bethe ansatz equations which diagonalize $H$ in (4) are

$$
Lk_{n_l} = -2\pi n_l + f_c\pi + \left(\frac{2M_{\text{odd}}}{N_{\text{odd}}} - 1\right)f_s\pi + \frac{2\pi}{N_{\text{odd}}} \sum_{\delta=1}^{M_{\text{odd}}} J_\delta,
$$

$$
Lk_{n_r} = 2\pi n_r + f_i\pi + \sum_{\gamma=1}^{M_{\text{even}}} \Theta(2\Lambda_{\gamma} - 2) - \pi],
$$

$$
N_{\text{even}}\Theta(2\Lambda_{\gamma} - 2) + \Theta(2\Lambda_{\gamma}) = 2\pi I_{\gamma} + (f_\uparrow - f_\downarrow)\pi + \sum_{\delta=1}^{M_{\text{even}}} \Theta(\Lambda_{\gamma} - \Lambda_\delta),
$$

where $k_{n_l}$ are the pseudomomenta characterizing the $N_{\text{odd}}$ odd-parity left movers which decouple from the impurity, $M_{\text{odd}}$ of which have spin down, and $k_{n_r}$ are pseudomomenta characterizing the $N_{\text{even}}$ even-parity right movers, $M_{\text{even}}$ of which have spin up. The numbers $n_l, n_r, I_\gamma$ and $J_\delta$ take integer or half-odd integer values depending on the values of $M_{\text{even/odd}}$ and $N_{\text{even/odd}}$ (see below), while $\{\Lambda_{\gamma}, \gamma = 1, \cdots, M_{\text{even}}\}$ are a set of auxiliary variables known as spin-rapidities. The scattering phase shifts are given by $\Theta(x) = 2\tan^{-1}(x/c)$, with $c = 2\Lambda/(1 - 3\lambda^2/4)$. We have also defined $f_{c/s} = (f_\uparrow \pm f_\downarrow)/2$. Eq. (18) simply gives the quantum numbers of free, chiral electrons, written in the Bethe ansatz basis. The Bethe ansatz equation (19) describes the charge degrees of freedom in the even channel (holons), while Eq. (20) describes the spin degrees of freedom in the even channel (spinons). Eqs. (13) and (20) differ from the Bethe ansatz equations derived previously for the Kondo model \[8\] only by the addition of the ABC fluxes $\phi_{\alpha} = f_{\alpha}\pi$.

Let us consider for the moment the case of a spin-independent flux $\phi_\alpha = \phi_{\downarrow} = \phi$, corresponding to the case where only a magnetic flux threads the ring and there is no charged string passing through the ring (AB flux only). The persistent current is an odd function of $\phi$ by symmetry, \[13\] and is analytic, except at values of $\phi$ corresponding to level crossings. We are interested in the persistent current for small values of the AB flux. Choosing the total numbers of both up- and down-spin electrons to be odd excludes a level crossing at $\phi = 0$. The leading mesoscopic behavior of the persistent current is then

$$
I(\phi) = -D_c\phi/L + O(\phi^3/L^3),
$$

where $D_c$ is the charge stiffness. Eq. (21) holds on general grounds independent of whether the model is integrable or not.

The choice of quantum numbers $\{n_l, J_{\delta}, n_r, I_{\gamma}\}$ specifies the quantum state of the system. Generically, there are one or more level crossings \[16\] between $f = 0$ and $f = 1$. To determine the charge stiffness, however, we only need to consider the state which evolves adiabatically from the ground state at $f = 0$ as $\phi$ is increased. This state is given by $M_{\text{even/odd}} = (N_{\text{even/odd}} / -1)/2$, (with $N_{\text{even/odd}}$ odd for simplicity), with integer-spaced quantum numbers $\{n_l, J_{\delta}, n_r, I_{\gamma}\}$ in the symmetric ranges $-(N_{\text{odd}} - 1)/2 \leq n_l \leq (N_{\text{odd}} - 1)/2$, $-(M_{\text{odd}} - 1)/2 \leq J_{\delta} \leq (M_{\text{odd}} - 1)/2$, $-(N_{\text{even}} - 1)/2 \leq n_r \leq (N_{\text{even}} - 1)/2$, and $-(M_{\text{even}} - 1)/2 \leq I_{\gamma} \leq (M_{\text{even}} - 1)/2$. The quantum numbers of the even-parity sector are the same as those of the Kondo model with periodic boundary conditions. \[8\]
Given a set of spin rapidities $\Lambda_{\gamma}$ satisfying Eq. (20), we may calculate the sum in Eq. (19), and thus the momenta $k_{nr}$ are determined. One sees immediately that the total scattering phase shift of the dressed magnetic impurity is independent of $f$, so that $N_r = -N_l = f/2$. In addition, the charge velocity $v_F$ is unrenormalized by interactions in this model. The charge stiffness may be evaluated from Eqs. (17) and (21) as a finite difference $D_c = -JI(f = 1)/\pi = ev_F/\pi + \mathcal{O}(L^{-2})$. This gives a lower bound to the charge stiffness, since an avoided level crossing in the nonintegrable regime $0 < \phi < \pi$ cannot be excluded. However, it is difficult to imagine on physical grounds how the magnetic impurity could enhance the persistent current, so we expect that this lower bound is an equality. The persistent current for small $\Phi$ is thus

$$I = -\frac{ev_F 2\Phi}{L \Phi_0},$$

which is identical to the result for free electrons. Eq. (22) indicates that spin-charge separation holds even at the mesoscopic scale in this model.

The analysis of the Bethe ansatz equations (18-20) in the case of general spin–dependent fluxes (however, still satisfying $\varphi_\alpha = f_\alpha \pi$ with $f_\alpha$ an integer) is more involved and will be presented elsewhere. However, an analysis of the equations (18-20) in the limiting cases $c \to 0$ and $c \to \infty$ indicates that the charge persistent current is markedly affected by the magnetic impurity when spin-dependent fluxes are present. This is because the AC effect induces a charge persistent current if the numbers of up and down spin electrons are not equal. As $c$ is increased from 0 to $\infty$, the impurity screens exactly one electron spin, so the effective numbers of mobile up and down spin electrons are not equal in general.
