(Dated: April 9, 2018)

We used inelastic neutron scattering to show that well below its Néel temperature, $T_N$, the two-dimensional (2D) XY nearly-triangular antiferromagnet YMnO$_3$ has a prominent central peak associated with 2D antiferromagnetic fluctuations with a characteristic life time of 0.55(5) ps, coexisting with the conventional long-lived spin-waves. Existence of the two time scales suggests competition between the Néel phase favored by weak interplane interactions, and the Kosterlitz-Thouless phase intrinsic to the 2D XY spin system.

Geometrical frustration and low dimensionality are the two key concepts in the statistical physics that provide unusual spin dynamics as well as phase transitions. A particular interest is placed on the unusual spin dynamics as well as phase transitions and/or low dimensionality in the systems. A broad peak was additionally observed at finite $Q$ around $T_N$, indicative of strong short-range spin correlations. However, due to intrinsic limitations of the powder diffraction technique, further experimental studies, especially inelastic single crystal neutron scattering measurements are necessary to understand the nature of the spin excitations.

In this paper, we report for the first time inelastic neutron scattering measurements on powder and single-crystal samples of the hexagonal rare-earth manganite YMnO$_3$. We have found that YMnO$_3$ is a good model system for the 2DXYTLAFM with weak trimerization. Our most important finding is that in the Néel phase there are fast 2D spin fluctuations with a characteristic time scale of 0.55(5) ps in addition to the conventional long-lived spin wave excitations. The inverse of dynamic correlation length associated with the fast 2D spin fluctuations has similar $T$-dependence as that expected for the KT phase in a 2D XY spin system, suggesting that the spin fluctuations are reminiscence of the KT phase. The coexistence of the long-lived magnons and the fast 2D spin fluctuations also suggests competition between the Néel phase and the KT phase in this quasi-2D XY spin system.

A 50 g powder sample and a 2 g ($\phi 5$ mm × 22 mm) single crystal of YMnO$_3$ were used in our neutron scattering measurements. Methods of sample preparation were reported elsewhere. Neutron scattering measure-
ments were performed at the NIST Center for Neutron Research. Powder experiments were performed at the Disk Chopper time-of-flight Spectrometer (DCS) using an incident energy of $E_i = 15.46$ meV and single crystal experiments at the cold neutron triple-axis spectrometer SPINS and the thermal neutron triple-axis spectrometer BT9. At SPINS, pyrolytic graphite (PG) 002 reflections were used for monochromator and analyzer, and a cooled Be filter was placed after the sample to eliminate higher-order contamination. We used horizontal collimations of 80′-80′ and a final energy $E_i = 5$ meV for most scans, while $E_i = 2.6$ meV and 80′-40′ were used when better energy resolution was needed. At BT9, the PG monochromator and analyzer were used with $E_i = 14.7$ meV, and a PG filter was used to get rid of higher order contamination.

Fig. 2 provides an overview of the inelastic neutron scattering experiments. Fig. 2 shows the representative constant-$\vec{Q}$ scans at the antiferromagnetic zone center $\Gamma$, namely, $\vec{Q} = (1, 0, 0)$ and equivalent positions. For $T > T_N$, the cooperative paramagnetic continuum appears as a quasielastic peak centered at $h\omega = 0$ meV. For $T < T_N$, the quasielastic peak intensity decreases and two prominent magnon peaks develop at nonzero energies. The energy values of the magnon peaks increase as $T$ decreases, becoming $h\omega \sim 5$ meV and weak scattering below.

Next, to obtain $\vec{Q}$-directional dependence of the magnetic excitations, we have performed single crystal inelastic scattering experiments. Fig. 3 shows the representative constant-$\vec{Q}$ scans at the antiferromagnetic zone center $\Gamma$, namely, $\vec{Q} = (1, 0, 0)$ and equivalent positions. For $T > T_N$, the cooperative paramagnetic continuum appears as a quasielastic peak centered at $h\omega = 0$ meV. For $T < T_N$, the quasielastic peak intensity decreases and two prominent magnon peaks develop at nonzero energies. The energy values of the magnon peaks increase as $T$ decreases, becoming $h\omega \sim 5$ meV and 5.3 meV at 7 K. A constant $\vec{Q} = (1, 0, 1)$ scan with a better energy resolution revealed an additional mode at $h\omega = 0.22$ meV (Fig. 3(e)).

We analyzed the observed spectra using the following scattering function with Lorentzians for the quasielastic and magnon peaks:

$$
\tilde{I}(\vec{Q}, h\omega) \propto h\omega[1 + n(h\omega)] \left[ I_{qel} \frac{\Gamma_{qel}}{\Gamma_{qel} + h\omega^2} + \sum_k I_{SW}^k \frac{\Gamma_{SW}}{\Gamma_{SW}^2 + (h\omega - h\omega_k)^2} \right].
$$

For $T > T_N$, there is a cooperative paramagnetic continuum centered at $Q = 1.2$ Å$^{-1}$ due to fluctuations of small AFM clusters, as is commonly found in geometrically frustrated AFMs. By integrating $I(Q, \omega)$ over $\omega$ and $Q$, we obtained the sum rule of $S(S + 1) = 5.2(5)$ at 80 K, which is close to the expected value for dynamic Mn$^{3+}$($S = 2$) ions. This and the $Q$ dependence tell us that the scattering is magnetic. For $T < T_N$, as the magnetic long range order develops, spectral weight at low energies gradually shifts to higher energies. At $T = 4$ K there is strong scattering above $h\omega \sim 5$ meV and weak scattering below. For most scans, while $E_i = 2.6$ meV, and its unit is arbitrary. Solid lines are fits to Eq. (2), whereas dashed lines represent the quasielastic part (see the text).
where $[1 + n(h\omega)] = [1 - \exp(-h\omega/k_B T)]^{-1}$. This function was convoluted with the instrumental resolution function to fit the observed spectra.

Let us first discuss the magnon dispersion relations at $T = 7$ K $< < T_N$. Fig. 4 shows the dispersion relations along a few high symmetry directions, obtained from several constant-$\vec{Q}$ and constant-$h\omega$ scans. To explain the observed dispersion relations, we introduce the following model-spin Hamiltonian:

$$\mathcal{H} = -\sum_{<ij>} J_{ij} \vec{S}_i \cdot \vec{S}_j - D_1 \sum_i (\vec{S}_i^2) - D_2 \sum_i (\vec{S}_i \cdot \vec{n}_i)^2,$$

which consists of two inplane ($J_1$ and $J_2$) and two interplane ($J'_1$ and $J'_2$) interactions, and the easy-plane ($D_1$) and inplane easy-axis ($D_2$) anisotropies (see Fig. 1 for the definition of the interactions). The anisotropy $D_2$, parallel to the spin directions ($\vec{n}_i = \langle \vec{S}_i \rangle/|\langle \vec{S}_i \rangle|$), is necessary to reproduce the small (0.22 meV) gap at the antiferromagnetic zone center, and is presumably due to the local structural distortion around Mn$^{3+}$. The conditions $J'_1 > 0$ and $J'_1 > J'_2$ are necessary for the particular interplane stacking in Y MnO$_3$ to be the ground state.

The model Hamiltonian is linearized using the Holstein-Primakoff approximation, and numerically diagonalized to obtain one-magnon dispersion relations using the standard equation-of-motion technique. Analytic expressions for the gap energies at the $\Gamma$ point were also derived assuming sufficiently small $D_2$. $J_1$ and $J_2$: $\omega_{\Gamma} \approx 2 \sqrt{-(D_2 \lambda_1)}$, $\omega_{2\Gamma} \approx 2 \sqrt{-(D_2 \lambda_2 - 2J'_1 - 2J'_2)}$, $\omega_{3\Gamma} \approx 2 \sqrt{(2D_1 \lambda_2 - 2D_2 \lambda_3 - 2D_1 J'_1)}$ and $\omega_{4\Gamma} \approx 2 \sqrt{2(D_1 \lambda_3 - D_2 \lambda_3 - D_1 (J'_1 + 2J'_2) - 2(J'_1 - J'_2) \lambda_3)}$ (from low to high energies), where $\lambda_1 = D_1 + (3/2)J_1 + 3J_2$, $\lambda_2 = (3/2)J_1 + 3J_2$ and $\lambda_3 = 2D_1 + (3/2)J_1 + 3J_2$. Fitting the calculations to the data, we obtained $J_1 = -3.4(2)$ meV, $J_2 = -2.02(7)$ meV, $J'_1 = J'_2 = 0.014(2)$ meV, $D_1 = -0.28(1)$ meV and $D_2 = 0.0007(6)$ meV.

Lines in Fig. 4 represent the calculated dispersion relations with $J'_2 = 0$. The good agreement confirms the validity of the model Hamiltonian. In the above, we could only determine the difference $J'_1 - J'_2$ for interplane interactions. From the analytic expressions we see that $h\omega_{3\Gamma}$ and $h\omega_{4\Gamma}$ must be accurately determined in order to obtain $J'_1$ and $J'_2$ separately. However, this was impossible since they appear as one peak at $h\omega = 5.3$ meV in Fig. 3(d) or 3(e) due to the insufficient energy resolution at high energies. Since the splitting between $h\omega_{3\Gamma}$ and $h\omega_{4\Gamma}$ becomes sensitive to $J'_1$ (or $J'_2$) at $\tilde{Q} = (1.05, 0, 0)$, we performed a constant-$\tilde{Q}$ scan at this $\tilde{Q}$ and found an almost resolution-limited peak at $h\omega = 5.4$ meV. This requires the splitting to be less than the energy resolution $\Delta E = 0.5$ meV, and consequently an upper limit of 0.08 meV is obtained for $J'_1$ and $J'_2$. Hence, the interplane interactions are at most 2.4 % of the inplane interaction $J_1$, evidencing the good two-dimensionality. One may note that $J_1 \sim J_2$, which makes YMnO$_3$ rather closer to the ideal TLAFM than a system of weakly coupled trimers. Our $J_1 \approx -3.4$ meV is one order of magnitude smaller than $J$ deduced in a recent Raman scattering study. They obtained $J \sim -140$ cm$^{-1}$ ($\sim -17$ meV) by assigning a broad peak appearing at 1800 cm$^{-1}$ ($\sim 220$ meV) to two-magnon scattering. However, our results clearly show that the peak cannot be due to the two-magnon process because the band width of the one-magnon branch is only about 16 meV. Their broad peak at 220 meV must be vibrational or electronic in origin rather than magnetic.

Now let us turn to the low energy quasielastic continuum observed below $T_N$, clearly seen in Fig. 3(b) and 3(c). For $T = 7$ K $< < T_N$, Fig. 3(c) shows a $h\omega = 0.55$ meV mode at $\tilde{Q} = (1, 0, l)$ with $l \neq 0$ which is due to inplane transverse spin fluctuations. The in-
plane transverse fluctuations cannot, however, appear at \( \vec{Q} = (1, 0, 0) \) because the polarization factor in Eq. (1) vanishes for the ordered spin structure in YMnO
tens. Note that such a mode does not show in Fig. 3(d). Therefore we rule out the inplane transverse spin fluctuations as the origin of the quasielastic continuum existing in the Néel phase. In order to understand the continuum, we performed constant \( h \omega = 1 \text{ meV} \) around \((1, 0, 0)\) at several temperatures and along different \( \vec{Q} \)-directions. Shown in Fig. 5(a) and 5(b) are representative scans at \( T = 40 \) K. A nearly resolution-limited peak is seen along the inplane \((1 + h, -2h, 0)\) direction whereas the intensity is independent of \( l \) perpendicular to the plane. These indicate that the quasielastic component is purely 2D in nature, well localized at the 2D antiferromagnetic zone center. Fig. 5(c) shows the temperature dependence of the intrinsic peak width along the \((1 + h, -2h, 0)\) direction. For \( T > T_N \) the width decreases almost linearly, whereas it becomes nearly resolution-limited below \( T_N \), indicating a large inplane correlation length at low temperatures. The energy width \( \Gamma_{qel} \) of the quasielastic peak is also shown in Fig. 5(d). \( \Gamma_{qel} \) decreases as \( T \) decreases down to \( T_N \) and saturates to a value of \( \Gamma_{qel} \approx 1.2(1) \text{ meV} \) below \( T_N \). It is surprising that the fast spin fluctuations with the characteristic time scale of \( \tau_{qel} = \hbar/\Gamma_{qel} \approx 0.55(5) \) ps coexist with the long-lived spin-waves in the Néel phase.

What is the origin of the fast 2D fluctuations in the Néel phase? Recently, a similar quasielastic peak, called central peak, has been found in numerical simulation studies on 2DXYTLAFMs. Theoretically, such a central peak has been commonly seen in 2D XY spin systems, triangular or non-triangular, and is related to the vortex dynamics intrinsic to the KT phase. We, thus, fitted our \( \kappa \) and \( \Gamma_{qel} \) to the phenomenological functions: \( \kappa = \kappa_0 \exp(-b/\sqrt{T}) \) and \( \Gamma = \Gamma_0 + A_2(\Lambda/h)e^{-2b/\sqrt{T}[(\sqrt{2} - 1)(\ln(k_B T_{KT}/\Lambda)/2 + b/\sqrt{T})]^{1/2}} \), where \( \tau = (T - T_{KT})/T_{KT} \) and \( \Lambda = J S^2a^2\kappa_0^2/4 \). Here if \( A = 1 \) and \( \Gamma_0 = 0 \), \( \kappa \) and \( \Gamma \) reduce to the analytical expressions for the 2D XY square lattice system. The best fit (solid lines in Fig. 5(c) and 5(d)) was obtained with \( T_{KT} = 11(10) \text{ K}, b = 10(4), \kappa_0 = 4(1) \text{ Å}^{-1}, A = 0.07(1) \) and \( \Gamma_0 = 1.2(1) \text{ meV} \). The fit reproduces \( \kappa \) and \( \Gamma \) well for the entire temperature range, suggesting that the quasielastic peak is reminiscent of the vortex dynamics. Coexistence of the magnons and quasielastic peak suggests competition between the Néel phase favored by the weak interplane interactions, and the KT phase intrinsic to the 2D XY spin system at low temperatures. It remains to be seen whether or not the prefactor \( A \) being smaller than 1 and the nonzero \( \Gamma_0 \) for the relaxation rate are intrinsic to the 2DXYTLAFM or are due to the competition between the two phases.

In summary, using inelastic neutron scattering measurements on a single crystal of the hexagonal antiferromagnet YMnO
tens, we have found in the Néel phase a central peak at the 2D AFM zone center which bears characteristics of the KT phase intrinsic to the 2D XY spin systems. Understanding in detail how the Néel and KT phases compete and change the nature of the dynamic spin correlations would require further theoretical and experimental studies in the 2D XY spin systems.
