Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China

A new kind of hydrophobic hyper-cross-linked polymers (HCPs) with high surface area, large pore volume, and controllable average pore size was prepared. The synthesized HCP-0.5 sample, having the biggest BET specific surface area (1394 m²/g), pore volume (1.55 m³/g) and micro-mesopore structure (average pore diameter of 4.4 nm), was used as a novel adsorbent for removing benzene. The results of the static adsorption/desorption experiment at 298, 308 and 318 K showed that HCP-0.5 has a very large adsorption capability of 19.16 mmol g⁻¹ at 298 K for benzene. Dynamic adsorption experiments of benzene on HCP-0.5 under dry and humid condition (RH = 80%) revealed that the existence of water vapor had little effect on dynamic adsorption capacity of benzene on HCP-0.5 and almost did not change the breakthrough time. Therefore, these synthesized polymers can be used as efficient and competitive adsorbents for removing VOCs, especially under humid conditions.

1. Introduction

Volatile organic compounds (VOCs) such as benzene, toluene, trichloroethylene and methanol are emitted from a wide range of industries [1]. In addition to posing detrimental effects on human health, such as carcinogenic effects, emissions of some VOCs also contribute to stratospheric ozone depletion, formation of photochemical smog and a number of toxic byproducts [1,2]. Due to these negative effects, VOCs have already received great attention in the field of environmental control.

Among these VOCs removal methods such as condensation, adsorption, catalytic oxidation and incineration [3,4], the VOCs adsorption on porous adsorbents is regarded as an economical and effective treatment process [5]. Activated carbon as a facile adsorbent is applied extensively to remove VOCs from process effluent stream due to its high surface area, abundant porosity, sustainability and a relatively high adsorption capacity [6–9]. Nonetheless, activated carbon adsorption always encounters some problems such as finite pore volume, combustion and pore blocking [10]. Moreover, the hydrophilic nature of activated carbon limits its application on VOCs removal from humid gas streams, due to the competition of water vapor with organic species for adsorption sites on activated carbon and the slow adsorption kinetics of VOCs [11,12]. Therefore, it is significant to develop new adsorbent materials with hydrophobic nature as a potential alternative for activated carbon to remove VOCs from polluted air streams.

In the past few decades, as a promising adsorbent for removing VOCs from a wide range of gaseous streams [13–17], porous organic polymers (POPs), especially hyper-cross-linked polymers (HCPs) have been investigated extensively in gas adsorption due
to its vast surface area, controllable pore structure, stable physical, chemical properties as well as low densities [18–20]. Moreover, hyper-cross-linked polymeric adsorbent without hydrophilic functional groups could possess a hydrophobic surface, which is beneficial for the removal of organic pollutants from humid gas streams.

In 2011, a versatile route to hyper-cross-linked polymers (HCPs) that avoids the need for monomers with specific polymerizable functionalities was demonstrated [21]. Li et al. used a simple one-step Friedel–Crafts reaction of a low-cost cross-linker with ordinary, low-functionality aromatic compounds as monomers to produce HCPs with high surface areas and large pore volumes. The major advantage of the new strategy is the wide range of monomers that are available. It provides a new approach for the synthesis of polymeric adsorbents with an excellent hydrophobic nature though selecting proper monomers.

In our previous paper [22], we synthesized a series of hyper-cross-linked polymers (HCPs) via a post-cross-linking reaction using low cross-linked polydivinylbenzene (PDVB) as precursor and 4,4′-bis(chloromethyl)biphenyl (BCMBP) as crosslinking reagent. The synthesized HCP-1.3 has high surface area, large pore volume and showed a good adsorption for benzene under water condition due to its high hydrophobic property. However, in our previous paper [22], we only studied the effect of the dynamic adsorption of benzene vapor containing 30% water vapor, and did not investigate the dynamic adsorption behavior of benzene on HCP-1.3 under higher humid conditions. In the latest work [23], we synthesized a conjugated polymer adsorbent with pure carbon chain backbone, which had excellent hydrophobicity and higher adsorption capacity of benzene than activated carbon. To explore a novel hyper-cross-linked polymeric adsorbent with good adsorption capacity to remove VOCs from air streams, in the present paper, we synthesize a new kind of hydrophobic HCPs by Friedel–Crafts alkylation (as shown in Scheme 1). Benzyl chloride was used as a monomer to enhance the adsorption capacities of hyper-cross-linked polymeric adsorbents for adsorbing VOCs from humid gas stream. Various amounts of formaldehyde dimethyl acetal (FDA) were used as an external cross-linker to investigate the effect of the ratios of cross-linker to monomer on pore structure of the polymeric products. HCPs-0.5 was selected as a model sample to investigate the adsorption property of the synthesized polymeric products. Benzene, one of the most common VOCs, was chosen as a representative adsorbate due to its high toxicity and volatility. Herein, static adsorption/desorption experiments at three different temperatures (298, 308 and 318 K) and dynamic adsorption experiments under dry and humid conditions (RH = 80%) of benzene on the synthesized polymeric product HCPs-0.5 were investigated.

2. Experimental

2.1. Synthesis of HCPs

Typically, 1.27 g benzyl chloride (10 mmol) and 0.38 g formaldehyde dimethyl acetal (FDA, 5 mmol) were added to 1,2-dichloroethane (DCE, 20 mL), followed by Iron (III) chloride (12 mmol). After stirring for 10 min at a room temperature, the mixture was heated to 45 °C for 5 h and then heated to 80 °C for 18 h. The solid product was removed out and washed with methanol until the filtrate was clear, then further purified by soxhlet extraction in methanol for 12 h and dried in vacuo at 60 °C for 18 h. The resulting polymers were denoted as HCP-X, where X refers to the molar ratio of the cross-linker to the monomer. In this work, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5 and 4.0 are selected as X values, respectively.

2.2. Characterizations

Textural properties of each sample were investigated using a BEL SORP-max gas adsorption analyzer by nitrogen adsorption and desorption at liquid nitrogen temperature (77 K). Samples were degassed at 120 °C for 12 h prior to analysis. Surface areas of samples were measured using the Brunauer–Emmett–Teller (BET) method. Pore size distributions of the porous materials were calculated using the density functional theory (DFT) method. The total pore volume was estimated from the amount adsorbed at a relative pressure of ≈0.99. The micropore volume was calculated by a t-plot method. Transmission electron micrograph (TEM) was performed on a JEOL JEM-2100 instrument. High resolution scanning electron microscope micrographs (SEM) were performed on a Hitachi S-4800 electron microscope, and the samples were sputter coated with platinum prior to measurement. Infrared spectra were collected on a Bruker Tensor 27 in the range of 400–4000 cm⁻¹ using KBr disks. The thermal gravimetric analysis (TGA) was carried out on a TA Instruments Q600SDT thermal analyzer. The heating rate was 10 °C min⁻¹ from 25 to 1000 °C under a nitrogen flow of 60 mL min⁻¹.

2.3. Static adsorption measurements

The static adsorption experiments were carried out using an Intelligent Gravimetric Analyzer (IGA) supplied by Hiden Analytical Ltd. with a high sensitivity of 0.1 mg. This apparatus is an ultrahigh vacuum system, which allows isotherms and the corresponding kinetics of adsorption and desorption to be determined by setting various pressures. The microbalance has a long-term stability of ±1 μg with a weighing resolution of 0.2 μg. The sample (60 ± 1 mg) was degassed at a pressure of <10⁻⁵ Pa at 393 K to remove the physically adsorbed impurities until it reached a constant weight. Pressure steps in the range of p/p₀ values from 0 to 0.98 were used to obtain the isotherm. The temperature of the sample was measured by a thermocouple that is located at 5 mm from the sample. The equilibrium uptake value was determined as being 90% of the predicted value, calculated in real time using the mass uptake profile. In the present work, 298, 308 and 318 K were selected as static adsorption temperatures, respectively. The saturated vapor pressures were calculated using the following equation [24]:

\[
\log_{10}p = A - \frac{B}{T + C}
\]

where p is the saturated vapor pressure (mbar), T is the temperature in (°C) and A, B and C are constants defined by the adsorbate: benzene (281–403 K): A = 6.90565, B = 1211.033, C = 220.79; water (263–383 K): A = 8.09533, B = 1747.32, C = 235.074.

![Scheme 1. Friedel–Crafts polymerization using formaldehyde dimethyl acetal.](image-url)
Dynamic adsorption measurements were carried out on a fixed-bed column. Detailed experimental conditions including the stock preparation of the analyte are corresponding with the experimental set-up and method described in our previous paper [23,25]. To reach and keep constant of the outlet concentration of benzene vapor, the flow rate of the carrier gas and the temperature of the saturator were adjusted. The benzene concentration was adapted to 530 ppm and the total flow rate was 50 mL min⁻¹. Before starting each experiment, the samples were degassed at 100 °C for 24 h to remove the impurities. Then, approximate 60 mg of sample was packed into a fixed-bed column (I.D. 6 nm). Benzene vapor was selected as an adsorbate and the temperature was maintained at 298 K. To investigate the effect of water vapor on the adsorption behavior, benzene with a concentration of 530 ppm in a relative humidity (RH) of 80% was passed through an adsorption column. The benzene concentrations in the feed and effluent streams were recorded on a gas chromatograph (GC) supplied by Agilent equipped with a flame ionization detector (FID) after being separated in an AB-GASPRO capillary column and the breakthrough curves were collected. The benzene adsorbed amounts by the sample which was packed in the column were calculated by the following equation [22]:

\[
Q = \frac{F_x t_q}{W}
\]

(2)

The time \( t_q \) is estimated according to Eq. (3):

\[
t_q = \int \left( 1 - \frac{C_i}{C_0} \right) dt - t_D
\]

(3)

where \( Q \) is the adsorbed amount (mmol g⁻¹); \( F_x \) is the volumetric flow rate of the carrier gas (mL min⁻¹); \( W \) is the net weight of adsorbent (g); \( C_i \) represents the benzene concentration at the inlet (g mL⁻¹), while \( C_o \) is the benzene concentration at the outlet (g mL⁻¹) and \( t_D \) is the breakthrough time of the system (min).

3. Results and discussion

3.1. Characterization of HCP-X

A series of polymeric materials was prepared using benzyl chloride as a monomer and various amounts of FDA as a cross-linker. All products are brown-black insoluble powders. The \( N_2 \) adsorption–desorption isotherms at 77 K over HCP-X samples are demonstrated in Fig. 1. It is observed that all the samples show a type I isotherm according to IUPAC classifications and the initial parts of the adsorption isotherms of all samples show a steep increase in nitrogen gas uptake \((p/p_0 < 0.01)\), indicating abundant microporous structure [22,26]. Compared with other samples, the adsorption isotherms of HCP-0.5 exhibit a remarkable rise and the desorption branch of the hysteresis loop is steeper than the adsorption branch at higher relative pressure \((p/p_0 = 0.3–1.0)\), indicating that a range of larger mesopores are presented in this polymeric material [27].

Pore size distributions of all polymeric samples are shown in Fig. 2. The most prevalent pores are centered below 2 nm, which indicates that the polymer is predominantly micropore. The peaks at region larger than 2 nm in pore size distribution demonstrate the existence of mesopore (2–50 nm) in the polymeric materials. The pore size distribution curves suggest the presence of both micropores and mesopores in all these polymers.

Detailed porosity properties of all polymeric materials prepared are presented in Table 1. It is clearly observed that by adjusting the monomer to cross-linker ratio, the BET surface areas and pore volumes can be controlled. The BET surface areas, total pore volumes and micropore volumes of samples decrease obviously and the average pore sizes slightly decrease with the increase of FDA amount. The highest BET surface area obtained is up to 1394 m²/g for HCP-0.5, while HCP-4.0 shows the lowest surface area of 784 m²/g. The HCP-0.5 sample shows the highest total pore volume (1.55 cm³/g) and the highest micropore volume (1.01 cm³/g).

As typical examples, Fig. 3 presents high-resolution SEM images and TEM images of HCP-0.5 and HCP-4.0 samples. High-resolution SEM images (Fig. 3(a) and (b)) show that two samples are composed of an amorphous lump morphology. As reported in literature [21], the lumps are formed by many nanospheres which adhere and accumulate together. The average diameters of the nanospheres of two samples are all less than 100 nm and the nanoparticle size of HCP-4.0 sample is slightly larger. It is also obvious that the nanospheres of HCP-4.0 sample adhere much closer than HCP-0.5 sample, which may be due to the higher extent of polymerization of the HCP-4.0 sample. TEM images (Fig. 3(c) and (d)) of the two samples further confirm the above results. From the TEM images of two samples we can observe the pores of HCP-0.5 sample and HCP-4.0 sample are disordered. HCP-0.5 sample shows the small and abundant nanospheres (Fig. 3(c)), while the HCP-4.0 sample gives relatively large extent of conglutination and accumulation (Fig. 3(d)). These results are in a good agreement with the observation by high-resolution SEM and nitrogen adsorption techniques. As a typical example, the FT-IR spectrum of HCP-0.5 is
shown in Fig. 4. The FT-IR spectrum is consistent with the expected networks showing aromatic benzene ring at ca. 1600 and 1660 cm\(^{-1}\), and the peaks at ca. 3030 and 1450 cm\(^{-1}\) are assigned to the vibrations of C–H in HCP-0.5 [28]. The detected absorbed band around 1265 cm\(^{-1}\) in curves is attributed to the wagging vibration of –CH\(_2\)Cl [22]. The TGA curve of HCP-0.5 is shown in Fig. 5. A small degree of weight loss around the temperature of 150 °C can be designated to a loss of adsorbed water on sample and the evaporation of residual organic solvents. The temperature of thermal decomposition for HCP-0.5 is greater than 400 °C. This result reveals that HCP-0.5 adsorbent exhibits a good thermal stability.

3.2. Static adsorption and desorption behaviors

It is widely recognized that apparent BET surface area and pore volume are two crucial factors that affect the adsorption capacity of adsorbent. The typical synthesized HCP-0.5 with a largest BET surface area and total pore volume was selected as a representative polymeric adsorbent to investigate the adsorption behavior for VOCs. The adsorption and desorption isotherms for benzene vapor over HCP-0.5 at 298, 308 and 318 K are shown in Fig. 6. Attributed to the existence of abundant microporous structure, the adsorption amount of benzene on HCP-0.5 increases faster at lower pressures.
As shown in Fig. 6, increasing the adsorption temperature from 298 to 318 K reduces the adsorption capacities of benzene on HCP-0.5, which is consistent with a physisorption mechanism. According to the IUPAC classification, the isotherms of benzene vapor at 298, 308 and 318 K are analogous with type II, indicating the monolayer adsorption at lower pressures and the multilayer adsorption at relatively higher pressures. The highest adsorbed amount of benzene on HCP-0.5 obtained at 298 K can reach up to 19.16 mmol g\(^{-1}\). The adsorbed amounts for benzene under static conditions over some other adsorbents are collected in Table 2 for comparison [29–32], which demonstrates the adsorption capability for benzene of HCP-0.5 is much higher than many classical pore absorbents reported. Although the adsorption capacity of HCP-1.3 in our previous work [22] is a little bigger than HCP-0.5 due to its greater surface area and pore volume, the simply one-step synthesis method of HCP-0.5 makes it a dominant position to remove VOCs from air streams.

For comparison, the adsorption property of water vapor on HCP-0.5 sample is also investigated by static measurements. The corresponding adsorption isotherms of benzene and water at three different temperatures (298, 308 and 318 K) are depicted in Fig. 7. According to the IUPAC classification, all the adsorption isotherms of water are of type III, which means the interactions between adsorbate and adsorbent are much smaller than the interactions between adsorbate and adsorbate during the adsorption process. The adsorption isotherm of water at 318 K exists a sharp increase in the quantity of gas adsorbed up to pressures nearing saturation (\(p/p_0\approx 0.85\)) as a result of capillary condensation of water. From Fig. 7, it shows clearly that the adsorption amounts of water on HCP-0.5 at different temperatures are much smaller than the adsorption amounts of benzene, which indicates the hydrophobic surface of HCP-0.5.

### 3.3. Virial equation

Adsorbate–adsorbent interactions can be quantified by comparing the uptakes under specific temperature/pressure conditions. Henry’s law constants \((K_H)\) at specific temperatures that is related to an affinity between an adsorbed gas molecules and an isosteric enthalpies of adsorption at a zero surface coverage \((Q_m, n = 0)\). The isosteric enthalpy of adsorption at the zero surface coverage is a fundamental measurement of an interaction of species with surfaces [33].

The virial equation can be written in the form [34]

\[
\ln \left( \frac{n}{p} \right) = A_0 + A_1 n + A_2 n^2 + \ldots
\]

where \(n\) is the amount adsorbed \((\text{mol g}^{-1})\) at pressure \(p\) (Pa). The first virial coefficient \(A_0\) is related to the Henry’s Law constant \(K_H\). At zero surface coverage the virial equation reduces to Henry’s Law; hence, \(K_H = \exp(A_0)\). The values of the first virial coefficient \(A_0\) reflects adsorbate/adsorbent interaction, whereas the second virial parameter \(A_1\) is a function of adsorbate/adsorbent interactions. In this study, analysis of the data showed that the \(A_2\) and higher terms in the virial equation can be ignored under conditions of low surface coverage.

Fig. 8 shows the virial graphs for benzene (Fig. 8(a)) and water (Fig. 8(b)) adsorption on HCP-0.5 at different temperatures (298, 308 and 318 K). Linear graphs of \(\ln(n/p)\) versus \(n\) for all the adsorption studied can be obtained at low surface coverage. The virial graphs of benzene at 298, 308 and 318 K are similar and distinguished with the virial graphs of water, obviously.

The virial parameters obtained from these graphs are shown in Table 3. \(A_0\) for benzene and water become more negative as the temperature increases, it is a result of weaker adsorbate–adsorbent interactions and this is consistent with the physisorption mechanism. \(K_H\) is dependent on the interaction between the adsorbed molecule and the adsorbent surface. From Table 3, it is obvious that the \(K_H\) values for benzene and water at 298, 308 and 318 K are in the order of benzene (298 K) > benzene (308 K) > benzene (318 K) > water (298 K) > water (308 K) > water (318 K).

The order is consistent with the physisorption mechanism. It is obvious that Henry constants \((K_H)\) for benzene are much greater than for water, due to the stronger adsorbate–adsorbent interactions between benzene and polymeric adsorbent, implying a good selectivity for benzene adsorption on polymeric adsorbent in humid environment.

### 3.4. Adsorption and desorption kinetics

A number of kinetic models for diffusion of molecules into polymeric adsorbent have been used. Linear driving force (LDF) model,
one of the most widely used uptake rate approximation, provides satisfac-
tory descriptions, in most cases, of the adsorption and des-
orption kinetics of the various gases/vapors on porous materials
depending on the adsorptive and experimental conditions. In the
present work, we selected the LDF model to simulate the adsorp-
tion–desorption kinetics of benzene over HCP-0.5 sample.

The LDF model for adsorption is described by the following
equation [35]:

\[
\frac{M_t}{M_e} = 1 - e^{-kt}
\]

(5)

where \(M_t\) is mass uptake at time \(t\), \(M_e\) is mass uptake at equilibrium
and \(k\) is the kinetic rate constant.

For a desorption process, a corresponding specific equation can
be described as follows:

\[
\frac{M_t}{M_e} = e^{-kt} - 1
\]

(6)

where \(M_t\) is the desorbed amount at time \(t\), \(M_e\) is the equilibrium
desorbed amount for the given pressure increment, and \(k\) is the des-
orbed rate constant.

Typical diagrams of \(\frac{M_t}{M_e}\) versus time \(t\) for the adsorption of
benzene and water on HCP-0.5 are shown in Figs. 9 and 10. Each diagram
shows that the adsorption behaviors of benzene and water on
HCP-0.5 obey the LDF model and represents pressure increments
in a different pressure region to prove that the model holds regard-
less of the position on the isotherm, indicating that diffusion
through a barrier at the pore entrance is the rate-determining step
during an adsorption process. The desorption kinetics that is similar
to the adsorption kinetics, comply the LDF model.

3.5. Effect of relative humidity on dynamic adsorption

A breakthrough curve measurement is a direct method to inves-
tigate the dynamic adsorption behavior of VOCs. The dynamic
adsorption experiments of benzene on HCP-0.5 under dry condi-
tion and humid condition (80% RH) were carried out using the
method described in the present paper. To elucidate quantitatively
the dynamic adsorption behavior of benzene and the effect of

![Fig. 8. Virial graphs for the adsorption of (a) benzene and (b) water on HCP-0.5 at 298, 308 and 318 K.](image)

![Fig. 9. Variation of \(\frac{M_t}{M_e}\) versus time for benzene and water adsorption on HCP-0.5 at 298 K. (a) Benzene: 58.15–58.60 mbar (\(p/p_0 = 0.4593–0.4629\)); (b) water: 21.20–
21.27 mbar (\(p/p_0 = 0.6667–0.6689\)).](image)
relative humidity on the adsorption, the breakthrough curves were fitted using the Yoon and Nelson model (Y–N model). The Y–N equation is expressed as the following [36].

\[
t = \frac{1}{k} \ln \left( \frac{C_b}{C_i} \right)
\]

where \(C_i\) and \(C_b\) are inlet and outlet concentration of adsorbate (mg L\(^{-1}\)), \(t\) is the adsorption time (min), \(k\) is the rate constant (min\(^{-1}\)), and \(\tau\) is the time required for 50% adsorbate breakthrough (min).

Fig. 11 shows breakthrough curves of benzene under dry and humid conditions (80% RH) in hyper-cross-linked polymer bed at 298 K. It is obvious that the breakthrough curves of benzene under dry conditions and wet conditions on HCP-0.5 are well fitted by the Y–N model. It is shown clearly that the presence of water changes a little the breakthrough curve when the relative humidity is 80%.

Table 4 summaries the calculated adsorption capacities and breakthrough time of benzene on HCP-0.5 based on the Y–N equation. The breakthrough time is calculated as the time at which the concentration of benzene in the outlet is 5% of the inlet concentration. From Table 4, it indicated that the breakthrough time decreased when water vapor exists and the decrease in the breakthrough time is less than 15%. Under dry condition, the breakthrough time of benzene on HCP-0.5 is 77.83 min, with a relatively low value of 66.41 min under the 80% relative humidity wet condition. The decrease in breakthrough time is due to the water adsorbed may hinder the diffusion of benzene in the pores. Due to hydrophobic property of HCP-0.5, the interactions between the water and the surface of the adsorbent are weaker than that between VOCs and the surface of the adsorbent, so the water adsorbed via pore filling can be displaced by benzene under the 80% relative humidity wet condition [37]. The dynamic adsorption amount of benzene on HCP-0.5 under 80% relative humidity reaches 86% of the corresponding value under dry condition as listed in Table 4, which indicates that high concentration of water vapor in a gaseous mixture will not significantly reduce the adsorption capacity of benzene on HCP-0.5. This finding further proves that the HCP-0.5 adsorbent has a hydrophobic surface property.

4. Conclusions

In summary, a new hyper-cross-linked polymer, hydrophobic HCPs, was successfully synthesized via one-step Friedel–Crafts alkylation reaction using benzyl chloride as a monomer, FDA as a cross-linker and FeCl\(_3\) as a catalyst. It is found that an HCP having a good hydrophobicity with high surface area and pore volume was formed under the investigated conditions. By adjusting benzyl chloride to FDA molar ratio, the HCP-0.5 sample having a high surface area of 1394 m\(^2\)/g, a large pore volume of 1.55 m\(^3\)/g and micro–mesopore structure was obtained. The static adsorption of benzene and water vapor was demonstrated over HCP-0.5 sample. The results indicated that the static adsorption amount of benzene obtained at 298 K is much greater than most of other classical adsorbents reported in literature. Henry’s law constant of HCP-0.5, calculated from virial equation, proved that the HCP-0.5 exhibited a good hydrophobicity. The dynamic adsorption results indicated that high concentration water vapor in benzene had little effect on the adsorption capacity of benzene on HCP-0.5. The dynamic adsorption amount of benzene on HCP-0.5 under 80% relative humidity can reach 86% of the corresponding value under dry condition and the breakthrough times are almost unchanged, which revealed that HCP-0.5 sample could exhibit high selectivity for the adsorption of benzene when water vapor coexists.
excellent adsorption performances of HCP-0.5 make this kind of material a potential candidate in removing VOCs, especially under humid conditions.
