Abstract. The reaction of α-pinene with NO₃ is an important sink of both α-pinene and NO₃ at night in regions with mixed biogenic and anthropogenic emissions; however, there is debate on its importance for secondary organic aerosol (SOA) and reactive nitrogen budgets in the atmosphere. Previous experimental studies have generally observed low or zero SOA formation, often due to excessive [NO₃] conditions. Here, we characterize the SOA and organic nitrogen formation from α-pinene + NO₃ as a function of nitrooxy peroxy (nRO₂) radical fates with HO₂, NO, NO₃, and RO₂ in an atmospheric chamber. We show that SOA yields are not small when the nRO₂ fate distribution in the chamber mimics that in the atmosphere, and the formation of pinene nitrooxy hydroperoxide (PNP) and related organonitrates in the ambient can be reproduced. Nearly all SOA from α-pinene + NO₃ chemistry derives from the nRO₂ + nRO₂ pathway, which alone has an SOA mass yield of 65(±9)%.

Molecular composition analysis shows that particulate nitrates are a large (60-70%) portion of the SOA, and that dimer formation is the primary mechanism of SOA production from α-pinene + NO₃ under simulated nighttime conditions. We estimate an average nRO₂ + nRO₂ → ROOR branching ratio of ~18%. Synergistic dimerization between nRO₂ and RO₂ derived from ozonolysis and OH oxidation also contribute to SOA formation, and should be considered in models. We report a 58 (±20)% molar yield of PNP from the nRO₂ + HO₂ pathway. Applying these laboratory constraints to model simulations of summertime conditions observed in the Southeast United States (where 80% of α-pinene is lost via NO₃ oxidation, leading to 20% nRO₂ + nRO₂ and 45% nRO₂ + HO₂), we estimate yields of 13% SOA and 9% particulate nitrate by mass, and 26% PNP by mole, from α-pinene + NO₃ in the ambient. These results suggest that α-pinene + NO₃ significantly contributes to the SOA budget, and likely constitutes a major removal pathway of reactive nitrogen from the nighttime boundary layer in mixed biogenic/anthropogenic areas.
1 Introduction

Monoterpenes (C\textsubscript{10}H\textsubscript{16}) are a major class of biogenic hydrocarbons. Although less abundant than isoprene in terms of absolute emission flux of non-methane hydrocarbons, they have a disproportionate importance for the formation of secondary organic aerosol (SOA), accounting for half of the total fine aerosol globally (Zhang et al., 2018), and for nitrogen oxide (NO, NO\textsubscript{2}, NO\textsubscript{3}) sequestration through the formation of gaseous and particle-phase organic nitrates (Pye et al., 2015). Thus, monoterpane chemistry plays a prevailing role in aerosol-climate interactions and atmospheric air quality. Of the monoterpenes, \alpha-pinene is the most abundant globally (Sindelarova et al., 2014). This is especially notable over boreal coniferous forests where the \alpha-pinene emission flux alone can overtake isoprene and the combined flux of all other monoterpenes during the summer season (Hakola et al., 2003). The atmospheric abundance, fast reaction rates, and nighttime emission profile of \alpha-pinene conspire for it to dominate the fate of the nitrate radical (NO\textsubscript{3}) in the dark, and also to play a significant role in the daytime (Ayres et al., 2015). The reaction of \alpha-pinene + NO\textsubscript{3}, thus, is one of the most prevalent reactions observed in the summer in mixed biogenic-anthropogenic sites, such as the Southeastern United States.

\textit{NO}\textsubscript{3} reacts with \alpha-pinene by addition to the double bond, mainly producing a nitrooxy alkyl radical in the tertiary position, which is rapidly converted to a nitrooxy peroxy radical (nRO\textsubscript{2}) upon collisions with molecular oxygen (Scheme 1). Prominent field observations of a monoterpane nitrooxy hydroperoxide ((\textit{O}:\textit{O}NO)ROOH) further suggest that the nRO\textsubscript{2} reacts with HO\textsubscript{2} significantly (Nguyen et al., 2015). However, laboratory research on \alpha-pinene + NO\textsubscript{3} has so far not demonstrated nitrooxy hydroperoxide formation, except for one experiment during the FIXCIT chamber studies where the pinene nitrooxy hydroperoxide (PNP) was abundantly produced from experiments using ppm-level concentrations of formaldehyde to produce dark HO\textsubscript{2} via the slow reaction of CH\textsubscript{2}O + NO\textsubscript{3} → HO\textsubscript{2} + HNO\textsubscript{3} (Nguyen et al., 2014a). Although we now appreciate that the nRO\textsubscript{2} from \alpha-pinene can form monoterpane nitrooxy hydroperoxide, its absolute yield is unknown; furthermore, such high concentrations of formaldehyde in the exploratory FIXCIT experiment will affect SOA formation, and thus, aerosol yields were not extractable.

Determinations of SOA yields of \alpha-pinene + NO\textsubscript{3} in the literature have also suffered from high uncertainty, although it has generally been accepted that the yields are lower than those of many other monoterpenes and, thus, often not considered for modeling SOA and organic nitrogen formation (Pye et al., 2015; Ayres et al., 2015). Fry et al. (2014) reported an SOA yield of exactly zero from this reaction from experiments using N\textsubscript{2}O\textsubscript{5} as an NO\textsubscript{3} precursor. Hallquist et al. (1999), Moldanova et al. (2000), Bell et al. (2021), and Mutzel et al. (2021) also reported low mass yields (0.3–7%, 0.3–6.9%, 3–11%, and 5.9–6.4% respectively, depending on precursor concentrations) with reactions performed similarly. Spittler et al. (2006) performed the experiment with slow and minute introductions of N\textsubscript{2}O\textsubscript{5} and reported higher mass yields, although they depend on whether

![Scheme 1: The NO\textsubscript{3}-initiated oxidation of \alpha-pinene produces a nitrated RO\textsubscript{2} radical (nRO\textsubscript{2}). The major isomer is shown.](https://doi.org/10.5194/acp-2021-703)
the seed particle chosen was ammonium sulfate (9%) or organic (16%). Nah et al. (2016) and Kurtén et al. (2017) also observed minimal SOA formation (mass yields of 3.6% and <1%, respectively) using NO$_2$ + O$_3$ as a source of NO$_3$, and formaldehyde to promote HO$_2$ chemistry. From these observations, it is clear that chamber reaction conditions are highly influential in the observed SOA yields, and that previous studies may have each probed different $n$RO$_2$ fates. Thus, a systematic investigation of how $n$RO$_2$ fates dictate reaction outcomes will enable reconciliation of past results and accurate representation of this reaction in atmospheric models. The high initial NO$_3$ concentrations (tens of ppb) used in some previous studies, derived from the decomposition of N$_2$O$_5$, will cause $n$RO$_2$ + NO$_3$ to dominate in the chamber, when it is negligible in the field ([NO$_3$] is persistently at or below the detection limit of 1 pptv in the rural Southeast United States; Ayres et al., 2015). Kjaergaard and coworkers further illuminated the role of alkoxy radical scission in SOA formation, and predicted low SOA yields from the $\alpha$-pinene + NO$_3$ reaction when the RO$_2$ radical is reduced to RO via bimolecular reaction with NO$_3$, RO$_3$, and even HO$_2$ (Kurtén et al., 2017).

Given the high relevance of the $\alpha$-pinene + NO$_3$ reaction, it is critical to place tighter constraints on how this reaction contributes to SOA and organic nitrogen in the ambient environment. In light of the emerging appreciation for the importance of RO$_2$ radical fate in designing chamber experiments (Nguyen et al, 2014a; Xu et al., 2019; Boyd et al., 2015; Teng et al., 2017; Crounse et al., 2013), we re-investigate this reaction to probe the SOA yield and organic nitrate formation from $\alpha$-pinene + NO$_3$ from each relevant $n$RO$_2$ reaction channel. While a chamber experiment may never truly replicate the field, and ours certainly are no exception, the $n$RO$_2$ fate distribution in this work was designed to approach those expected in the ambient nighttime (Ayres et al., 2015; Romer et al., 2018), including any reaction synergies that may occur (Kenseth et al., 2018; Inomata, 2021). Finally, relatively little information is available for the $n$RO$_2$ compared to their hydroxylated counterparts; this work also constrains the rate coefficients and branching ratios of the $\alpha$-pinene $n$RO$_2$ through a combination of chamber reactions and modeling. We demonstrate a new HO$_2$ formation route in the dark chamber that does not require carbon inputs, and thus enables SOA yields to be more accurately measured when probing the RO$_2$ + HO$_2$ pathway from the $\alpha$-pinene + NO$_3$ reaction.

## 2 Methods

### 2.1 Chamber reactions

Experiments were performed in a 10 m$^3$ FEP Teflon atmospheric chamber in the dark in the dark and at a temperature of $\sim$22 °C, consistent with the average nighttime temperatures in the Southeastern United States in the summer (Hidy et al., 2014). Experiments were performed dry to reduce uncertainty from variable wall loss corrections and avoid rapid hydrolysis of tertiary nitrates (Vasquez et al., 2021), and because RH is not expected to influence radical reactions. Temperature and RH were monitored continuously by a membrane probe (Vaisala Inc.) calibrated with saturated salt solutions. NO$_x$ and O$_3$ mixing ratios were quantified with commercial chemiluminescence (Thermo 42i) and photometric (Thermo 49i) analyzers. The
A chemiluminescence analyzer was calibrated with a NO₂ primary standard (200 ppmv, Air Liquide) diluted to desired concentrations using ultra-high-purity (UHP) N₂ and zeroed with UHP N₂. The photometric analyzer was cross calibrated for O₃, produced by an ozone generator (A2Ozone Inc.) from ultra zero air (Air Liquide), with a Fourier-transform infrared spectrometer (FT-IR, Shimadzu Scientific Inst. Inc., IR-Tracer 100) using a 10 m gas cell. α-Pinene mixing ratios were quantified with a gas chromatograph coupled to a flame ionization detector (GC-FID) using a PLOT-Q column (Agilent Inc.) and a custom pneumatically-injected method. The GC-FID was calibrated with a NIST-traceable 40 ppm α-pinene primary standard in N₂ (Matheson Gas) diluted to several concentrations with UHP N₂ using calibrated mass flow controllers (SEC, Horiba Inst. Inc.). The mass flow controllers were calibrated using a primary flow calibrator (AP Buck, Inc.).

Table 1. Initial conditions for chamber experiments performed in this work. Controls to subtract SOA yields from background chemistry (not listed here) were conducted for experiments 1-11 and 17-25 using identical conditions but omitting of NO₂.

| Expt | Type       | pinene (ppb) | H₂O₂ (ppm) | O₃ (ppb) | NO₂ (ppb) | NO (ppb) | N₂O₅ (ppb) | Mixing time (min) | seed area (µm²/cm³) | seed mass (µg/m³) |

Initial conditions for all chamber experiments are described in Table 1. The chamber was cleaned prior to each experiment by continually flushing with custom-filtered zero air, quantified to be below the detection limits of all available analyzers, for at least 12 hours (>7 full air exchanges). Two types of experiments were conducted: those using O₃ + NO₂ as an NOₓ source, and those using N₂O₅ as an NOₓ source. For the former, variable concentrations of NO₂ (diluted from 2042 ppm ±1% in N₂, Praxair) and O₃ were injected to initiate the formation of low levels of NO₃, according to the desired nRO₂ fate. H₂O₂ (50 wt.% in H₂O, Aldrich) was then injected by flowing 4 L min⁻¹ of ultra zero air through a bubbler warmed to 40 °C in a water bath. After the inorganic gas-phase reactants were introduced, the chamber was allowed to mix for 1-2 h, during which time secondary formation of NO₃ (from O₃ + NO₂) and HO₂ (from NO₃ + H₂O₂) could proceed. Seed particles were introduced to the chamber during mixing by atomizing a solution of 0.06 M ammonium sulfate ((NH₄)₂SO₄, ≥99%, Aldrich) through a ²¹⁰Po neutralizer. Lastly, liquid standards of α-pinene (Sigma Aldrich, ≥99%) were injected with gas-tight syringes into an airtight glass bulb, and introduced to the chamber by a 4 L min⁻¹ flow of ultra zero air. The α-pinene reacts quickly and thus was mixed rapidly from pulsed injections of high pressure ultra zero air (100 psi) for 2 min in order to initiate the reaction.

The ozonolysis of α-pinene occurs concurrently with its NO₃-initiated oxidation with this experiment design. Ozonolysis of α-pinene produces OH, which reacts with H₂O₂ to be an additional dark formation source of HO₂, as well as with α-pinene itself. Control reactions were performed to accompany each experiment listed in Table 1 that includes ozone, using the same conditions minus NO₂, in order to subtract out the SOA and other product formation from the purely ozonolytic reaction.

For experiments that used N₂O₅ as the NOₓ source, injections of α-pinene and other desired inorganic reactants, including seed particles, NO₂, and NO (200 ppm ±1% in N₂, Praxair), were conducted first. The reactions were then initiated by the rapid injection of gas-phase N₂O₅, which was previously evaporated into an evacuated 500 mL glass bulb to the desired pressure and backfilled to room pressure with N₂. N₂O₅ was synthesized according to Claflin and Ziemann (2018), verified using FT-IR, and stored in the dark at -20°C prior to use. In these experiments, the decomposition equilibria of N₂O₅ ⇌ NO₂ + NO₁ was manipulated via injections of NO₂ in order to slow NO₃ formation and thus control the nRO₂ fate.

During experiments, mixing ratios of oxygenated gas-phase organics were quantified with a custom-built triple-quadrupole chemical ionization mass spectrometer (CIMS) using CF₃O⁻ as the reagent ion. Instrumental details, including humidity-dependent calibration methods, have been described in detail previously (Crounse et al., 2006; St. Clair et al., 2010; Nguyen et al., 2014b; Praske et al., 2015). The CIMS detects PNP and other polar analytes predominantly without fragmentation as clusters with CF₃O⁻. Although authentic standards of PNP are not available for direct calibration in CIMS, the analytical sensitivity of synthesized organic nitrates of different carbon length and neighboring groups in the CF₃O⁻ CIMS were found to be different from each other by a factor of 20-30% (Lee et al., 2014; Teng et al., 2017); thus, sensitivity of PNP and pinene hydroxy-nitrate were assumed to be the same as isoprene hydroxynitrates with 30% uncertainty.

A scanning mobility particle sizer (SMPS), comprised of an electrostatic classifier (TSI 3080) and a condensation particle counter (TSI 3772), was used to measure particle size distributions between 15 nm and 670 nm. Control experiments monitoring the dark decay of ammonium sulfate seed aerosol concentrations in the chamber were used to determine diameter-
dependent particle wall loss rates (Schwantes et al., 2019), which were then used to correct experiment particle concentrations. Calculations of particle mass from measured aerodynamic diameter assume a density of 1.2 g cm\(^{-3}\).

### 2.2 Kinetic modelling

We use a kinetic model (Mech. S1) to simulate gas-phase chemistry for each experiment in the environmental chamber. The mechanism uses reaction parameters from the JPL Chemical Kinetics and Photochemical Data Evaluation (Burkholder et al., 2019), and is run on Matlab (MathWorks, Inc.). We also include reactions of \(\alpha\)-pinene with OH, O\(_3\), and NO\(_3\), and isomer-specific reactions of the subsequently produced peroxy radicals with HO\(_2\), NO, NO\(_3\), and other RO\(_2\) radicals (individually represented). Product yields from each pathway, along with rates of RO\(_2\) + RO\(_2\) reactions, are adjusted to fit the experimental data. We initialize simulations with the inorganic species listed in Table 1, and allow the model to run for the allotted mixing time before instantaneously adding pinene. The model does not include any wall deposition of vapors or gas-particle interactions, and is used only to estimate the concentrations of gas-phase species and the contributions of each peroxy radical reactive pathway.

### 2.3 SOA composition analysis by high-resolution mass spectrometry (HRMS)

SOA were collected for composition analysis using Omnipore hydrophilic Teflon filters (0.2 \(\mu\)m diameter pore, Millipore Corp.) that is compatible with polar and non-polar organics. The filters were gently extracted using LC-MS grade acetonitrile (Optima, Fisher Scientific) to mass concentrations on the order of 100 \(\mu\)g/mL, depending on the experiment, by several ultrasound pulses of duration 1 s in order to limit cavitation in the ultrasonic bath that may alter analyte compositions. Filter extracts were directly infused into a linear-trap-quadrupole (LTQ) Orbitrap XL mass spectrometer (Thermo Instrument Corp.) using positive and negative ion mode electrospray ionization (ESI) at 4 kV spray voltage and a mass resolving power of 60,000 \(m/\Delta m\) at \(m/z\) 400. An external calibration was performed in both ion modes using commercial mass standards in the range of 100 – 2000 \(m/z\) (Pierce™ LTQ ESI Positive and Pierce™ LTQ ESI Negative calibration solutions, Fisher Scientific), and the data were recalibrated until the mass accuracy obtained from standard solutions was < 1 ppm.

The data analysis was performed similarly to our previous works (Nguyen et al., 2010; Nguyen et al., 2011). Briefly, the raw data were de-convoluted using Decon2LS (freeware from Pacific Northwest National Laboratory), and background subtracted for peaks present in the solvent. The \(m/z\) peaks were assigned to molecular formulas (C\(_{c}\)H\(_{h}\)O\(_{o}\)N\(_{n}\)) based on a custom Matlab script that applies Lewis and Senior rules (Kind and Fiehn, 2007) and a Kendrick Mass Defect analysis (base CH\(_2\); Roach et al., 2011) that have been demonstrated on SOA mixtures. The prevalent ionization mechanism for this specific analyte mixture was found to be sodium cluster formation (M+Na\(^+\)) in the positive mode, which occurs preferentially for carbonyls (Kruve et al., 2013), and nitrate cluster formation (M+NO\(_3\)-) in the negative mode, which is efficient for organic nitrates, alcohols, and other functional groups (Sisco and Forbes, 2015; Mathis and McCord, 2005). The nitrate anion, prominently detected in the mass analyzer at \(m/z\) 61.988, was not purposefully introduced but likely formed either from in-source fragmentation of organic nitrates or from HNO\(_3\) produced during the hydrolysis of tertiary organonitrates from the aqueous
LC solvents, and fortuitously acted as a reagent ion for chemical-assisted electrospray. While peak heights correlate well with concentration in direct-infusion ESI HRMS when the analyte matrix is similar (Chan et al., 2020), the correlation coefficients are unknown for each analyte in the mixture; thus, the HRMS data is qualitative. Furthermore, due to the labile –ONO₂ groups, the organonitrate observations from HRMS likely represent a lower limit.

3 Results and discussion

3.1 SOA and PNP yields from different nRO₂ fates

To investigate the dependence of aerosol and gaseous PNP yields on the nRO₂ reaction partner, we performed a series of environmental chamber experiments (experiments 1-16, Table 1) with various starting conditions designed to isolate or maximize the contributions of each RO₂ reaction pathway. Example time profiles from three representative experiments are shown in Figure 1. nRO₂ + NO₃, nRO₂ + NO, and nRO₂ + RO₂ chemistry were isolated in experiments using N₂O₅ as the NO₃ source. Using excess N₂O₅ as a source causes a rapid initial spike of NO₃, making the nRO₂ + NO₃ pathway easy to isolate in

Figure 1. Modelled (solid lines) and measured (points) concentrations of key reactive species and products in three example chamber experiments. Timing of chamber injections are demarcated at top. Experiment time of 0 corresponds to the beginning of a-pinene oxidation. Pie charts show the percent contribution of each a-pinene oxidative pathway (a-pinene + O₃ in red, a-pinene + OH in grey and a-pinene + NO₃ speciated by subsequent RO₂ reaction partner: orange for NO₃, blue for RO₂, green for HO₂).
Experiment 13 (Fig. 1, left). The $n$RO$_2$ + NO pathway is similarly easy to isolate with excess NO added before N$_2$O$_5$ injection, as in Experiment 15. $n$RO$_2$ + $n$RO$_2$ chemistry can be maximized by injecting excess $\alpha$-pinene prior to N$_2$O$_5$ addition; the NO$_3$ is thus dominantly consumed by reaction with $\alpha$-pinene, leaving the subsequently produced $n$RO$_2$ to react with each other, as in Experiment 26 (Fig. 1, middle), for which we calculate that 79% of $n$RO$_2$ reacted with other $n$RO$_2$. $n$RO$_2$ + HO$_2$ chemistry is more difficult to isolate due to the scarcity of clean HO$_2$ sources in the dark. Here, we describe a method that can achieve a domination of $n$RO$_2$ + HO$_2$ chemistry without additional carbon inputs, initiated by the slow production of NO$_3$ in situ via NO$_2$ + O$_3$, which will introduce three reaction partners for $\alpha$-pinene (NO$_3$, O$_3$, OH). Alkene ozonolysis has been used previously to produce dark OH in chamber experiments (Xu et al., 2019); Leveraging the ozonolysis of $\alpha$-pinene already occurring in the chamber, we can amplify HO$_2$ production by injecting excess H$_2$O$_2$ prior to $\alpha$-pinene to scavenge OH. Thus, the OH + H$_2$O$_2$ $\rightarrow$ HO$_2$ + H$_2$O reaction simultaneously produces HO$_2$ and suppresses the side chemistry of $\alpha$-pinene + OH. This HO$_2$ source is relevant to the nighttime atmosphere, as ozonolysis is always occurring with NO$_3$ reaction in the ambient due to the major source chemistry from NO$_2$ + O$_3$.

The added H$_2$O$_2$ provides an additional benefit – its reaction with NO$_3$ is a source of HO$_2$ prior to $\alpha$-pinene injection (Fig. S1). The H$_2$O$_2$ + NO$_3$ $\rightarrow$ HO$_2$ + HNO$_3$ reaction has been estimated by Burrows, Tyndall, and Moortgat (1985) to have an upper limit of $<2 \times 10^{15}$ cm$^3$ molec$^{-1}$ s$^{-1}$ – too slow for atmospheric relevance, but sufficient to produce significant HO$_2$ in chambers when H$_2$O$_2$ is in excess. The rate coefficient of this reaction was further constrained from its upper limit based on the ratio of $k_{CH_2O+OH}/k_{CH_2O+NO3}$ (Burkholder et al., 2019), resulting in a rate coefficient of $1.1 \times 10^{16}$ cm$^3$ molec$^{-1}$ s$^{-1}$ used in our simulations. The formation of PNP was not adequately reproduced if HO$_2$ is assume to originate from H$_2$O$_2$ + OH alone, i.e., omitting the H$_2$O$_2$ + NO$_3$ reaction in the kinetic model; the yield of PNP would need to be unphysically high to reconcile the difference.

The $\alpha$-pinene + NO$_3$ reaction is modeled to be the major $\alpha$-pinene sink in experiments initiated by NO$_2$ + O$_3$ (e.g., 73% in Experiment 22, Fig. 2, Table 2). Even so, the background chemistry from $\alpha$-pinene + O$_3$ and $\alpha$-pinene + OH (from the ozone control experiments without NO$_2$) are substantial sources of SOA and require careful subtraction (Fig. 2). Caveats to this approach include: (1) in the controls, ozone and OH are larger sinks for $\alpha$-pinene due to a lack of competition from NO$_3$; thus, a larger fraction of $\alpha$-pinene produces SOA from ozonolysis in the control compared to the experiment and the subsequent subtraction obtains a lower-limit SOA yield;
synergistic reactions between RO$_2$ intermediates from the different oxidation pathways are not possible to isolate, and contributed roughly 20% to the analytical signal from the SOA composition analysis (Section 3.3); however, it is now appreciated that these synergies also occur in the ambient and are not realistic to ignore in laboratory and modeling studies (Kenseth et al., 2018; Inomata, 2021).

These ‘simulated nighttime’ experiments (e.g. Experiment 20, Fig. 1, right) are termed as such because they provide an atmospherically relevant balance of reactive pathways, in which fractional contributions are comparable to those on summer nights in the Southeast United States (60–80% $\alpha$-pinene + NO$_3$, 20–40% $\alpha$-pinene + O$_3$; 30–50% $n$RO$_2$ + HO$_2$, 30–50% $n$RO$_2$ + RO$_2$; Ayres et al., 2015; Romer et al., 2018). This is corroborated by gas phase data from the CIMS (Fig. 3), which show that NO$_3$-initiated products are the major volatile products formed in the simulated nighttime experiments. Furthermore, these experiments are able to reproduce gaseous organonitrates observed during the Southern Oxidant and Aerosol Study (SOAS; Carlton et al., 2018), including PNP – a major monoterpene semivolatile at the SOAS site in rural Alabama – and an unknown compound at m/z 314 that has also been observed in the ambient with similar time profiles to PNP (Fig. S2).

Product yield results from different $n$RO$_2$ reaction pathways are shown in Table 2, along with the modeled contributions of each $n$RO$_2$ reaction pathway. We observe low SOA formation in experiments maximizing $n$RO$_2$ + NO$_3$ (3(±3)% mass yield, Experiment 13) and $n$RO$_2$ + NO (12(±7)%; Experiment 15). This is consistent with previous observations of 0–16% SOA mass yields from N$_2$O$_5$-initiated experiments (in which the $n$RO$_2$ + NO$_3$ pathway tends to dominate), where the larger yields were obtained only with slow continuous introductions of N$_2$O$_5$ (Bell et al., 2021; Fry et al., 2014; Hallquist et al., 1999; Moldanova et al., 2000; Muutzel et al., 2021; Spittler et al., 2006). We also observe no correlation between SOA yields in ‘simulated nighttime’ experiments and the fractional contribution of the $n$RO$_2$ + HO$_2$ pathway (Fig. S3), suggesting no SOA production from this pathway, consistent with Kurten et al. (2017) and Nah et al. (2016). This result conforms to expectations as $n$RO$_2$ + HO$_2$ produces either the RO radical (Iyer et al., 2018) leading to the volatile pinonaldehyde (Kurten et al., 2017) or the hydroperoxide, which has high enough volatility to be observed by the CIMS. We do, however, observe high yields of SOA in experiments targeting $n$RO$_2$ + $n$RO$_2$ chemistry (up to 82% mass yield, Experiment 26). This includes both N$_2$O$_5$-initiated experiments with excess $\alpha$-pinene and O$_3$ + NO$_2$ + H$_2$O$_2$-initiated ‘simulated nighttime’ experiments, during which we measured SOA mass yields of 19–55%.
Table 2. Peroxy radical pathway contributions and measured experimental outcomes for experiments performed in this work.

| Expt | X(HO$_2$)$_i$ (ppt) | X(NO$_3$)$_i$ (ppt) | X(RO$_2$)$_{max}$ (ppb) | Modelled | Measured |

*a* not measured

Across all experiments, the modeled fractional contribution of the $n$RO$_2$ + $n$RO$_2$ pathway correlates strongly with SOA yield (Fig. 4a). An error-weighted linear regression (York et al., 2004) of ozonolysis-corrected SOA yield against the modeled $n$RO$_2$ + $n$RO$_2$ contribution suggests a 67% mass yield ($R^2 = 0.54$) from this pathway alone. With such a large number of experiments spanning a range of different pathway contributions, however, we can improve upon this simple fit by performing a multivariate linear regression to estimate SOA yields from all pathways, with coefficients limited to be ≥0. This results in a
predicted SOA mass yield from the \( nRO_2 + nRO_2 \) pathway identical to results from the simple linear estimate within error: 65(±9)%. SOA mass yields from the other pathways are not significantly different from zero within uncertainty: 11(±11)% for \( nRO_2 + NO \), 3(±7)% from \( nRO_2 + NO_3 \), 0(±5)% from \( nRO_2 + HO_2 \). Results from this regression analysis, which gives an R\(^2\) of 0.62 against measured SOA yields, are shown in Figure 4b. Repeating the regression analysis for all \( \alpha \)-pinene sinks in the ‘simulated nighttime’ experiments, including the ozonolysis and OH pathways as additional independent variables, also gives coefficients indistinguishable within error (0% for \( \alpha \)-pinene + OH, 18% for \( \alpha \)-pinene + O\(_3\)).

These fits intrinsically depend on kinetic model parameters such as bimolecular RO\(_2\) reaction rates, some of which are uncertain. While we are unable to fully quantify these rates, we find that certain ratios between rates are constrained by our experimental outcomes. For example, the negligible SOA yield in the high-NO\(_3\) Experiment 13 suggests that \( nRO_2 + nRO_2 \) chemistry cannot play a major role in that experiment. This can only be achieved if the bulk rate coefficient for \( nRO_2 + nRO_2 \) reactions (\( k_{RO_2+RO_2} \)) is approximately two orders of magnitude slower than that of \( nRO_2 + NO_3 \) reactions (\( k_{RO_2+NO_3} \)). We therefore set the bulk \( k_{RO_2+RO_2} \) to 1×10\(^{-13}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\) (with the corresponding bulk \( k_{RO_2+NO_3} \) equal to 1×10\(^{-11}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\)), but we note that this rate likely represents a weighted mean of different rates for the different \( nRO_2 \) isomers (Orlando and Tyndall, 2012), and that it remains uncertain. Higher \( k_{RO_2+RO_2} \), which has been suggested elsewhere for pinene (Berndt et al., 2018), would necessitate a much higher \( k_{RO_2+HO_2} \) rate in ‘simulated nighttime’ experiments, a value that is better constrained (Boyd et al., 2003). A slower bulk rate of 1×10\(^{-14}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\) would scale the contribution of \( nRO_2 + nRO_2 \) chemistry in the ‘simulated nighttime’ experiments by a factor of 0.67, which in turn would require scaling SOA yields from this pathway up by 50%.

To constrain the sequestration of reactive nitrogen under ambient conditions from the \( \alpha \)-pinene + NO\(_3\) reaction, we also quantify PNP yields in our simulated nighttime experiments. Figure 5 (top) shows measured PNP molar yields as a function of the \( nRO_2 + HO_2 \) fate contribution. Regression analysis (York et al., 2004) suggests a branching ratio for PNP formation of 58(±2)% from \( nRO_2 + HO_2 \) (R\(^2\) = 0.88), which we implement in our kinetic model (Fig. 5, bottom). Including
the uncertainty in the CIMS calibration increases the uncertainty bounds to 58(±20)%. The bulk yield likely represents a combination of different branching ratios to PNP formation from the different $n$RO$_2$ isomers. We hypothesize that the secondary (minor) $n$RO$_2$ produces exclusively PNP in its reaction with HO$_2$, which would imply a branching ratio of 37% for PNP formation from the tertiary (major) $n$RO$_2$ + HO$_2$, assuming an initial branching of 65:35 major:minor isomers from α-pinene + NO$_3$ (Jenkin et al., 1997; Saunders et al., 2003). Our measured bulk PNP yield is somewhat higher than the 30% estimated in the FIXCIT studies (Kurtén et al., 2017), which used similar instrumentation but slightly different chamber conditions (formaldehyde instead of H$_2$O$_2$ and slow addition of α-pinene to minimize RO$_2$ + RO$_2$ chemistry). Some of this discrepancy might be explained by an overestimate of the contribution of $n$RO$_2$ + HO$_2$ chemistry in the FIXCIT experiment, where they assumed that all NO$_3$ produced by O$_3$ + NO$_2$ reacted with α-pinene and that all $n$RO$_2$ reacted with HO$_2$ (Kurtén et al., 2017).

We also detect α-pinene hydroxy nitrate (PHN), a product of $n$RO$_2$ + $n$RO$_2$ chemistry, and α-pinene dinitrate (PDN), a product of $n$RO$_2$ + NO or $n$RO$_2$ + NO$_3$ chemistry, by CF$_3$O - CIMS. Based on similar regression analyses of observations and modeling results (Fig. S4), we estimate a bulk PHN yield from $n$RO$_2$ + $n$RO$_2$ of 11.7(±3.3)%. However, because the major $n$RO$_2$ isomer (with the tertiary peroxy radical) is unable to donate an α-hydrogen for PHN formation, a bulk yield of 11.8% represents a 34% branching ratio from the minor (secondary) $n$RO$_2$ isomer (assuming an initial ratio of 65:35 major:minor isomers from α-pinene + NO$_3$. Jenkin et al., 1997; Saunders et al., 2003). While observed PDN correlates with $n$RO$_2$ + NO$_3$ chemistry, its low signal and uncertain CIMS sensitivity makes quantification difficult.
this effect and ensure that RO₂ fate experiments (#1-16) were initiated with sufficient seed aerosol, we performed an additional set of experiments (#17-25) under ‘simulated nighttime’ conditions to investigate the dependence of SOA yield on seed surface area (Fig. 6). No SOA formation was observed in the absence of seed aerosol, indicating that α-pinene + NO₃ does not nucleate. This is in contrast to our ozonolysis control experiments where nucleation was observed, in agreement with other accounts (Burkholder et al., 2007; Hoppel et al., 2001; Inomata, 2021; Takeuchi et al., 2019). The lack of nucleation is consistent with the expectation that the α-pinene + NO₃ reaction dominates the nighttime experiments over ozonolysis. SOA yields reached a maximum when initial seed surface area reached 143 µm² cm⁻³ (equivalent under experimental conditions to 5.3 µg m⁻³). This threshold is at least an order of magnitude lower than those measured by Schwantes et al. (2019) for SOA from isoprene OH oxidation under high-NO conditions and by Zhang et al. (2014) for SOA from toluene oxidation, suggesting much lower volatility for the α-pinene + NO₃ products.

3.3 SOA molecular composition

Filters collected following SOA formation in Experiments 26 (high nRO₂ + nRO₂), 27 (simulated nighttime), and the ozonolysis control (without NO₂) for Experiment 27 were analyzed by HRMS to determine the SOA molecular composition (Figure 7). As expected, the mass spectrum from the ‘simulated nighttime’ experiment (#27, Fig. 7B) exhibit substantial overlap with those from the N₂O₅-initiated experiment in which the nRO₂ + nRO₂ pathway dominated (#26, Fig. 7D), corroborating the results in Section 3.1 that suggested the nRO₂ + nRO₂ pathway is responsible for most SOA formation from α-pinene + NO₃ chemistry. The SOA from nRO₂ + nRO₂ chemistry is dominated by compounds containing 17-20 carbon atoms, suggesting that dimerization is the primary mechanism by which nRO₂ + nRO₂ reactions lead to SOA formation.

Masses in the ‘simulated nighttime’ SOA that are also observed in the nRO₂ + nRO₂ control experiment (#26) account for 39% of the negative mode peak signal and 29% of the positive mode peak signal in the SOA from the ‘simulated nighttime’ experiment. Negative mode may overestimate the contributions from dinitrates dimers from nRO₂ + nRO₂, whereas positive mode may underestimate them. In the positive mode, it was also found that 34% of the peaks in the ‘simulated nighttime’ experiment can also be found from ozonolysis chemistry (including OH reaction), 14% of peaks are found in both ozonolysis and nRO₂ + nRO₂ chemistry, and 24% of peaks are completely unique to the nighttime chemistry. SOA from α-pinene ozonolysis is dominated by oxygenated monomers in the negative mode and lacks organonitrate functionalities, making it easy
to distinguish from the mass spectrum of NO$_3$-oxidized SOA. The peaks from α-pinene ozonolysis can thus be subtracted off from the ‘simulated nighttime’ SOA mass spectrum, leaving a spectrum attributable to α-pinene + NO$_3$ under ‘simulated nighttime’ conditions (Fig. 7C).

The signal-weighted composition of SOA from the ‘simulated nighttime’ reaction (Fig. 7B), which includes background ozonolysis, is 60–70% nitrogen-containing organics with 1–3 nitrate groups, as determined in both negative and positive mode (where organic nitrogen species are not enhanced). Of the organic nitrogen, it appears that 2N species are the most abundant and comprise ~30% of the SOA on average. This suggests dimerization from $n$RO$_2$ + $n$RO$_2$ to form C$_{14-20}$ compounds is highly important to SOA formation. Previous analyses of the molecular composition of SOA from α-pinene + NO$_3$ have also found a dominant contribution of dimers in the particle phase (Bell et al., 2021; Takeuchi et al., 2019). The 0N, 1N, and 3N species may also be dimers (4N were not highly observed), as each of the expected RO$_2$S from all channels can have 0–2 N (Fig. 8). There is also a clear population of trimers from α-pinene SOA that is observed here (Fig. 7, m/z centered...
around 700, with associated carbons C21-C30) and elsewhere (Claflin and Ziemann, 2018; Romonosky et al., 2017) that may suggest RO2s can react with neutral compounds to propagate RO2 radicals that then terminate with another RO2.

**Scheme 2.** Proposed mechanisms for the formation of stable products (red) from α-pinene + NO3 oxidation, including nitrooxy-hydroperoxide (PNP), α-pinene hydroxynitrate (PHN), pinene dinitrate (PDN), the oxidation product observed by CIMS at m/z 314, and pinonaldehyde, as well as α-pinene-derived peroxy radicals (nRO2α-ϕ, blue) that may contribute to particle-phase dimers (Fig. 8) following the dominant secondary addition of NO3 to α-pinene. “X” stands in for any of RO2, HO2, NO, or NO3 as bimolecular reaction partners.

The data show that SOA formation from α-pinene + NO3 originates from a varied cohort of distinct nRO2 isomers. In **Scheme 2** we suggest multiple pathways involving bimolecular reactions, β-scission, and intramolecular isomerization that can produce different C7-C10 nRO2 isomers following the initial reaction of α-pinene with NO3. These pathways are consistent with RO2 chemistry previously suggested from theoretical (Kurtén et al., 2017) or lab studies (Xu et al., 2019) of similar systems. Some reactions of nRO2 with NO, NO3, or HO2 shown in **Scheme 2** propagate nRO2 radicals due to unimolecular decomposition rather than forming stable products; this implies that dimer-containing SOA from nRO2 can originate from all nRO2 fate pathways. **Figure 8C** shows the most abundantly observed dimers in the SOA from nRO2 + nRO2 chemistry (labeled peaks a-d in **Fig. 7D**), which include C20H30O4 (α-α, **Fig 7D.a**; presumably following the loss of 2 HONO from dimer C20H32N2O8 in the ESI source), C17H26N2O10 (δ-α, **Fig 7D.b**), C20H32N2O10 (β-β, **Fig 7D.c**), and C20H31N3O13 (ε-α, **Fig 7D.d**). Bell et al. (2021) also observed C20H32N2O8 and C20H32N2O10 among the most abundant compounds in SOA from α-pinene + NO3 chemistry in which nRO2 + nRO2 reactions were thought to dominate.

Dimers from the ozonolysis control experiments are notably absent from the ‘simulated nighttime’ experiment. This is likely because the peroxy radicals from α-pinene ozonolysis, which would have reacted with each other to dimerize in the
ozonolysis-only experiment, instead react with the more abundant $nRO_2$ radicals from $\alpha$-pinene + NO$_3$ in the ‘simulated nighttime’ experiment. This dimerization from cross-reactions of peroxy radicals from both oxidation pathways is responsible for the ~24% additional HRMS signals in the $\alpha$-pinene + NO$_3$ SOA spectrum (Fig. 7C; black peaks) but not in the $nRO_2$ + $nRO_2$ SOA spectrum (Fig. 7D). Figure 8D show how RO$_2$s formed from ozonolysis (i-iii; Iyer et al., 2021), initially via the vinylhydroperoxide channel, and OH reactions (1-2; Xu et al., 2019) can couple with $nRO_2$s to produce synergistic dimers during nighttime oxidation of $\alpha$-pinene. This type of synergy is missing when lab studies cleanly isolate reaction pathways, but may be an important part of SOA formation in the ambient as reactions occur simultaneously (Teng et al., 2017). These results underscore the importance of conducting chamber experiments under atmospherically relevant conditions.

While we do not seek to represent each individual $nRO_2$ and dimerization pathway in our kinetic model, we adjust the product yields from the first-generation $nRO_2$ + $nRO_2$ reactions to provide a reasonable estimate of dimer formation. The observed combined positive and negative mode peak signal attributable to C$_{14-20}$ compounds (presumed dimers) in $nRO_2$ + $nRO_2$ SOA (Experiment 27, Fig. 6D) constitutes 40-60% of the total signal. To produce this 40-60% of the 65% SOA mass yield estimated from $nRO_2$ + $nRO_2$ chemistry in Section 3.1 using dimers, assuming a mean dimer molar mass of 485 g mol$^{-1}$ (the average of the positive mode and negative mode peak-signal-weighted mean), requires a molar yield of 0.18 dimer molecules from the $nRO_2$ + $nRO_2$ reaction (0.09 per $nRO_2$). This bulk effective yield represents an average across the various $nRO_2$ + $nRO_2$ isomer permutations; branching ratios from individual $nRO_2$ + $nRO_2$ isomer reactions may differ substantially.

### Figure 8.

Structures and molecular formulas for (A) $nRO_2$ from NO$_3$-initiated chemistry (Scheme 2), (B) RO$_2$ from OH or O$_3$ chemistry (Xu et al., 2019; Iyer et al., 2021), (C) prominent dimers observed from $nRO_2$ self/cross reactions, and (D) dimers from synergistic $nRO_2$ + RO$_2$ couplings observed in the ‘simulated nighttime’ reactions. Dimers with chemical formulas written in pink are uniquely observed in the ‘simulated nighttime’ experiments; those marked with a * have moderate-to-high signal (40>SN).
but in our kinetic model we simply apply the bulk effective yield to all peroxy radical self- and cross-reactions. This 18% dimer yield is somewhat higher than has previously been measured in other systems (Orlando and Tyndall, 2012), including from α-pinene ozonolysis (Zhao et al., 2018), but fits with recent evidence suggesting that increased molecular size and functionalization can significantly increase dimer branching ratios (Molteni et al., 2019; Berndt et al., 2018).

4 Conclusions and atmospheric relevance

Contrary to previous chamber experimental results, we have shown here that the reaction of α-pinene with NO₃ can form high mass yields of SOA (>21%, at ~30 ppbv of α-pinene) under RO₂ fate branching ratios designed to mimic those of summer nights in the Southeast United States. Much of this SOA originates from the self- and cross-reactions of nitrated peroxy radicals (nRO₂ + nRO₂); we estimate that this pathway alone has an SOA mass yield of 65%, with an associated dimer branching ratio of ~18%, while SOA formation from other nRO₂ pathways is negligible within uncertainty. This hypothesis is also supported by the dominance of dimers in the ozonolysis-subtracted mass spectra of SOA collected from ‘simulated nighttime’ experiments, the diversity of which suggests that many different peroxy radical rearrangements and dimerization channels contribute to SOA formation from nRO₂ + nRO₂ chemistry.

The magnitude of α-pinene concentrations in the Southeast United States will be lower than that used in our chamber; thus, we model the α-pinene + NO₃ chemistry at nighttime concentrations measured during the SOAS campaign in rural Alabama in the summer (1 ppb α-pinene, 1 ppb other terpenes, 20 ppb ozone, 1 ppt NO₃, and 2 ppt HO₂; Ayres et al., 2015; Romer et al., 2018) and assuming steady-state for nRO₂. At atmospheric concentrations, our kinetic model predicts that 80% of α-pinene reacts with NO₃. Of the nRO₂ formed, approximately 20% is predicted to react with α-pinene-derived nRO₂ or α₃RO₂ at k₉RO₂+RO₂ to 1×10⁻¹⁴ cm³ molecule⁻¹ s⁻¹. Combined with our measured 65% SOA mass yield from nRO₂ + RO₂, this suggests an overall SOA mass yield of 13% from α-pinene + NO₃ chemistry under the ambient conditions of SOAS. This SOA yield corresponds to a 9% particulate nitrate yield for compounds that did not hydrolyze. The mass of the –ONO₂ group alone represents 13% of the SOA mass. A rough calculation predicts that the nighttime reaction of 1 ppbv (~ 5.5 µg/m³) α-pinene may produce ~0.65 µg/m³ SOA (~0.44 µg/m³ of which is particulate nitrates) through its reaction with NO₃. These calculations neglect cross reactions of nRO₂ with other terpene RO₂, estimated to comprise another 20% of the nRO₂ fate, which may also lead to SOA formation. Although the yields in this work would predict α-pinene + NO₃ represents a significant fraction of aerosol and particulate nitrate mass observations during SOAS, previous modeling efforts did not track the SOA or organic nitrates from α-pinene + NO₃ due to belief that this reaction does not produce aerosol (Pye et al., 2015; Ayres et al., 2015). Atmospheric models should therefore include SOA formation from α-pinene + NO₃, ideally with a dependence on nRO₂ fate.

Since HRMS analysis suggests that most compounds in α-pinene + NO₃ SOA retain their organonitrate functionality, they will become a permanent sink of NO₃ following particle deposition. The α-pinene + NO₃ chemistry can also have important implications for reactive nitrogen budgets in the gas phase. The high yield of PNP (58%) from nRO₂ + HO₂ will
temporary sequester NOy, which may become a permanent sink when the PNP undergoes deposition (Nguyen et al., 2015) or retains its nitrate functionality following further oxidation. Approximately 45% of nRO₂ is expected to react with HO₂ during the conditions of SOAS; thus, the nighttime reaction of 1 ppbv α-pinene is expected to produce ~260 pptv of volatile PNP.

During SOAS, PNP is observed with maximum concentrations of ~30 pptv, possibly limited by its atmospheric deposition and transport, among other fates (Nguyen et al., 2015). Together, both particle and gas-phase organonitrate formation and deposition from α-pinene + NO₃ chemistry may amount to a substantial removal pathway for atmospheric NOₓ.

Our results also highlight the necessity of performing chamber experiments under conditions that more closely match those in the ambient atmosphere. Measured SOA yields depend heavily on the reactive fate of RO₂ in chamber experiments. Previous experiments using N₂O₅ as a source of NO₃ to study SOA formation from α-pinene + NO₃ likely observed low mass yields due to the dominance of nRO₂ + NO₃ reactions, from which we observe little-to-no SOA formation. Similarly, experiments that maximize nRO₂ + HO₂ may observe primarily volatile products. Only in experiments designed to allow sufficient nRO₂ + nRO₂ reactions was SOA formation observed. Furthermore, HRMS analysis shows that a large fraction of the compounds in SOA formed under ‘simulated nighttime’ conditions are not observed in either ozonolysis-only or nRO₂ + nRO₂-only SOA, suggesting that synergistic reaction pathways can enhance SOA formation when multiple oxidation channels occur simultaneously. Because ozonolysis and NO₃ oxidation occur together at night in the atmosphere, chamber experiments isolating one or the other will necessarily be biased in their representation of nighttime SOA from α-pinene and potentially other volatile hydrocarbons.

**Code and data availability.** Chamber experiment data are available online at the Index of Chamber Atmospheric Research in the United States (ICARUS; https://icarus.ucdavis.edu/). The chemical mechanism for kinetic modelling can be found in the Supplement (Mech. S1).

**Author contributions.** T. B. N., K. H. B. and G. J. P. B. designed the chamber experiments. K. H. B. and G. J. P. B. performed the chamber experiments. K. H. B. performed the kinetic modelling. J. D. C. assisted with chemical syntheses and experiments. T. B. N. and K. H. B. prepared the manuscript.

**Competing interests.** The authors declare that they have no conflict of interest.
