(Dated: April 6, 2021)

Here we report the optical and x-ray absorption (XAS) spectra of the wide-band-gap oxide MgO using density functional theory (DFT) and many-body perturbation theory (MBPT). Our comprehensive study of the electronic structure shows that while the band gap is underestimated with the exchange-correlation functional PBEsol (4.58 eV) and the hybrid functional HSE06 (6.58 eV) compared to the experimental value (7.7 eV), it is significantly improved (7.52 eV) and even overcompensated (8.53 eV) when quasiparticle corrections are considered. Inclusion of excitonic effects by solving the Bethe-Salpeter equation (BSE) yields the optical spectrum in excellent agreement with experiment. Excellent agreement is observed also for the O and Mg K-edge absorption spectra, demonstrating the importance of the electron-hole interaction within MBPT. Projection of the electron-hole coupling coefficients from the BSE eigenvectors on the band structure allows us to determine the origin of prominent peaks and identify the orbital character of the relevant contributions. The real space projection of the lowest energy exciton wavefunction of the optical spectrum indicates a Wannier-Mott type, whereas the first exciton in the O K-edge is more localized.

I. INTRODUCTION

MgO is one of the most extensively studied oxides which is used as a substrate material and in various heterostructures with applications related to tunneling magnetoresistance [1–3]. As a wide band gap insulator with a measured optical band gap of 7.7 [4] from absolute-reflectance measurements with UV radiation and 7.83 eV [5] from thermoreflectance spectroscopy, this material is employed e.g. in transient x-ray spectroscopy and time-dependent density-functional theory (DFT) calculations aiming to unravel the propagation of excitations across the interface in metal-insulator heterostructures [6–9]. Understanding spectroscopic features from first-principles requires accurate modeling beyond the ground state properties including excitations of different origin and energy scale.

The structural and electronic properties of MgO have been widely studied with first-principles calculations [10–12]. DFT calculations with semilocal functionals yield a fundamental band gap of 4.88, 4.50 and 4.76 eV [10, 12, 13], respectively. Many-body perturbation theory (MBPT) calculations employing Hedin’s GW approximation [14] render an increased fundamental gap of 6.8 and 7.25 eV [11, 12], respectively, which is still lower than the experimental one.

The optical spectrum, calculated by Wang et al. [13] using the local density approximation (LDA) as the exchange-correlation functional for the DFT calculation and subsequently including GW and excitonic corrections agrees with experiment [15] w.r.t. peak positions up to 12 eV whereas the amplitude of the peaks beyond the first one is overestimated due to the limited number of unoccupied bands employed in the BSE corrections. Schleife et al. [10] studied the frequency-dependent dielectric function for different MgO polymorphs – wurzite, zinc blende, and rocksalt – in the independent particle (IP) approximation using the generalized gradient approximation in the PW91 parametrization [16]. Good agreement with experiment concerning the peak positions was obtained by including excitonic corrections with BSE, based on the Kohn-Sham (KS) eigenenergies and a scissors operator to describe the QP eigenenergies [17, 18].

While optical spectroscopy probes excitations from valence bands, x-ray absorption spectroscopy (XAS) probes those from the strongly localized core states. A common approach to model XAS is the final state rule (FSR) [19] based on Fermi’s Golden rule, where the effects of screening of the core-hole (the so-called final-state effects) are calculated in a supercell. Alternatively, XAS can be described by considering quasiparticle and excitonic effects within MBPT by using GW and solving the BSE. Rehr et al. [20] showed that while both approaches led to similar overall features in the O and Mg K-edge spectra of MgO, BSE calculations result in better agreement with experiment at high transition energy due to the non-local treatment of the exchange interaction. Recent implementations of BSE in all-electron codes [21, 22] with explicit treatment of core states have demonstrated very good agreement with experiment for the XAS spectra of TiO2 (rutile and anatase), PbI2, and CaO [22]. The latter approach is adopted in this work.

Here we describe both the optical and x-ray absorption spectra of bulk MgO including many-body effects. As a first step, we perform the $G_0W_0$ corrections starting from Kohn-Sham (KS) wavefunctions. We show that careful consideration of the electron-hole interaction with BSE is essential to achieve agreement with experiment for both valence and core excitation spectra. In particular, the op-
tactical spectrum calculated with two different DFT functionals (PBEsol and HSE06) including the $G_0W_0$ and BSE corrections are consistent with experiment [4, 23] and previous theoretical work [17, 18] and yield an improved agreement regarding the intensity of the peaks at higher energies, highlighting the importance of quasiparticle and excitonic effects.

Previous studies have shown that a dense k-mesh is required for the sampling of the Brillouin zone to describe sufficiently the localization of the excitonic wave function and the fine structure in the vicinity of the absorption edge [11]. Here, we use a model for the static screening with parameters fitted to the $G_0W_0$ calculation, to solve the BSE (so-called model BSE [11, 24]) starting directly from DFT wavefunctions on a denser k-mesh, which improves in particular the low energy range (7–11 eV). The results for the model BSE are presented in Appendix B. Beyond previous work we provide a thorough analysis of interband transitions contributing to the peaks in the optical spectrum. Further insight into the nature of the first bound exciton is given by the real-space visualization of its wave function.

Employing the exciting code, the O and Mg K-edge XAS spectra calculated with BSE show very good agreement with the experimental spectra [25] and with previous theoretical results using the FSR [20]. Knowledge of the origin of peaks is essential for the interpretation of X-ray spectra. The main incentive of this study is to identify the nature of transitions which contribute to the peaks and analyze the character of the first exciton in the O K-edge both in real and reciprocal space.

The paper is structured as follows: the details of the calculations are presented in Section II, followed by the discussion of the results in Section III. We start with the electronic properties of MgO in III A and then compare the optical spectra calculated with two different starting exchange-correlation functionals in III B. Subsequently, we analyze the transitions in reciprocal space to derive the origin of contributions to the peaks in the spectrum. In subsection III C, we present the XAS spectra of the O and Mg K-edge and identify the underlying transitions in reciprocal space for the prominent peaks. Finally, subsection III D is dedicated to the real-space visualization of the first exciton of the optical and the O K-edge x-ray absorption spectrum. The results are summarized in Section IV, followed by two appendices showing a comparison of the optical spectra obtained with VASP and exciting and the optical spectrum with the model BSE.

II. COMPUTATIONAL DETAILS

The DFT calculations are performed with the VASP code (version 5.4.4) [26, 27], using pseudopotentials in combination with the projector augmented wave (PAW) method [28], and the exciting code [29] (version Nitrogen) employing the all-electron full-potential (linearized) augmented planewave + local orbital ([L]APW+lo) method. For the exchange-correlation functional we chose the generalized gradient approximation (GGA) in the implementation of Perdew, Burke, and Ernzerhof (PBE96) [30], PBEsol [31, 32], and the hybrid functional, HSE06 [33, 34]. The equilibrium lattice constant determined with the different functionals amounts to 4.24 Å (PBE96), 4.21 Å (PBEsol), and 4.20 Å (HSE06), the experimental one being 4.212 Å [35]. For the calculation of the optical spectrum with VASP, we have performed single-shot $G_0W_0$ on top of the KS wavefunctions obtained with two DFT functionals, PBEsol and HSE06 and subsequently included excitonic corrections by solving the BSE. For all the BSE calculations the Tamm-Dancoff-approximation (TDA) [36] is adopted. The calculations are performed for a two-atom unit cell with a Γ-centered $15 \times 15 \times 15$ k-mesh (unless otherwise specified) with a plane-wave cut-off energy of 650 eV. GW PAW pseudopotentials for excited properties were employed in all the calculations with two valence electrons for Mg: 3$s^2$ and six for O: 2$s^2$, 2$p^4$. 192 unoccupied bands are used for both the DFT and single-shot $G_0W_0$ calculations with 100 frequency-grid points. For the optical spectrum a Lorentzian broadening of 0.3 eV is used.

Employing PBEsol [31, 32] as the starting exchange-correlation functional for the ground-state calculation, single-shot $G_0W_0$ calculations are also performed with the exciting code [29] together with BSE [37] (within TDA) for the optical and x-ray absorption spectra [22]. A Γ-centered $11 \times 11 \times 11$ mesh shifted by (0.09, 0.02, 0.04) a.u. is employed for the calculations. Muffin-tin radii of 1.058 Å for Mg and 0.767 Å for Mg and O, respectively, are used with a basis set cut-off $R_{MT}|G + k|_{max} = 7$, and the lattice constant is set to the PBEsol value of 4.21 Å. The energy threshold to include the local field effects in the excited properties, $|G + q|_{max}$, is set to 4.5 a.u. for the optical and O K-edge, and 1.5 a.u. for the Mg K-edge absorption spectra. The exchange-correlation functional PBEsol is employed for the Kohn-Sham (KS) states and a total of 192 unoccupied bands are considered in the ground state and $G_0W_0$ calculation for the optical and O and Mg K-edge x-ray absorption spectra. For the optical spectrum in the BSE calculation, four occupied and five unoccupied bands are considered, while eight unoccupied bands were taken into account for the XAS spectra. A Lorentzian broadening with a width of 0.55 eV is applied to the spectra to mimic the excitation lifetime. The atomic structures and isosurfaces are visualized with the VESTA software [38] and the band structure is calculated with the Wannier90 [39] package in VASP.

III. RESULTS

A. Electronic properties

We start our analysis by comparing the electronic properties obtained from DFT calculations with three
different functionals, namely PBE96, PBEsol and HSE06. Table I presents the band gap calculated with VASP. With PBE96 (4.49 eV) and PBEsol (4.58 eV), the band gaps are considerably underestimated, consistent with previous calculations [10–12]. On the other hand, HSE06 renders a band gap of 6.58 eV closest but still below the experimental value of 7.7 and 7.83 eV [4, 5]. The $G_0W_0$ band gap obtained with PBEsol (7.52 eV) is closest to experiment, whereas a somewhat lower value (7.26 eV) is obtained with PBE96 which is in agreement with the value of 7.25 eV from Ref. [12]. The latter study [12] has also addressed the effect of self-consistent quasiparticle correction cycle on the optical properties: self-consistency in $GW$ while keeping $W_0$ constant ($GW_0$) increased the band gap to 7.72 eV, while fully self-consistent $GW$ led to an overestimated band gap of 8.47 eV and was attributed to the missing vertex corrections in the self-consistency cycle. While the size of the band gap may be reproduced by considering (partial) self-consistency in $GW$, our results show that the inclusion of excitonic effects (see Sections III B and III C) is essential in order to describe the relevant features and the shape of the spectrum. We note that the $G_0W_0$ band gap with the hybrid HSE06 functional is also overcorrected (8.53 eV). This is consistent with previous findings that the effects of the starting exchange-correlation functional are large at the independent-particle level, but the differences are reduced when considering quasiparticle [40] and eventually excitonic effects [41].

Since PBEsol and HSE06 provide better electronic properties as compared to PBE96 we continue the analysis with those. In Fig. 1a the Kohn-Sham and $G_0W_0$ band structure with the PBEsol functional is plotted along high-symmetry points, showing a direct $(\Gamma - \Gamma)$ band gap. The inclusion of quasiparticle effects in the $G_0W_0$ calculation leads to a nearly rigid shift of the unoccupied Kohn-Sham bands to higher energies. The top of the valence band (VB) consists mainly of O $2p$ states (cf. the projected density of states in Figs. 1b-d) with low dispersion along the $L - \Gamma - K$ direction, whereas the lower bands are more dispersive. Further insight into the orbital-resolved contributions of O and Mg on the band structure is provided in Fig. 2. The bottom of the conduction band (CB) comprises hybridized O $3s$, $3p$, and Mg $3s$ states that are highly dispersive along the $L - \Gamma - X$ and $K - \Gamma$ directions (cf. Figs. 1c, d and Figs. 2a, b, and d). In the range of 4.5 - 11 eV beyond the CB minimum, $3s$, $3p$, and Mg $3s$ states prevail, whereas above 11 eV O $3p$ states become predominant, followed by Mg $3p$ and $3d$ states above 15 eV (cf. Fig. 1d and Figs. 2e, f). We will further analyze the ion- and orbital projections in the band structure in Section III B 3 and Section III C to correlate the contributions with the optical and XAS spectra.

| $E_{xc}$ | DFT | $G_0W_0$ | Experiment |
|----------|------|-----------|------------|
| $E_\text{g}$ (eV) | PBE96 | 4.49 | 7.26 | 7.7$^a$ |
| $(\Gamma - \Gamma)$ | PBEsol | 4.58 | 7.52 | 7.83$^b$ |
| | HSE06 | 6.58 | 8.53 | |

$^b$ Reference 5

B. Optical properties

Starting from the electronic structure presented in the last section, we determine the optical spectrum including also many-body effects. We discuss the effect of approximations to the exchange-correlation functional, namely PBEsol and HSE06, on the spectra and the role of inclusion of $G_0W_0$ and excitonic corrections with BSE. In ad-
dition, the interband transitions responsible for the spectral features are analyzed in reciprocal space.

1. Optical spectrum within IP approximation and inclusion of $G_0W_0$ corrections

The calculated optical spectra are plotted in Fig. 3 together with the experimental ones [4, 23]. The imaginary part of the experimental dielectric function shows four prominent peaks (marked in Fig. 3b): the first two at $\sim 7.7$ eV and 10.7 eV are of nearly equal intensity, the third and fourth peak are at 13.32 and 16.9 eV, respectively, with a smaller intensity of the latter. We start our analysis by considering the results from the independent particle (IP) approximation using the KS eigenvalues calculated with the functionals PBEsol and HSE06. The imaginary part of the dielectric function has its onset at 4.58 and 6.58 eV for PBEsol and HSE06, respectively, below the experimental spectrum, due to the underestimation of the band gap (cf. Table I). Moreover, prominent peaks in the imaginary part of the spectrum are observed at $\sim 8.5$, 11, and 15.5 eV for PBEsol and at around 11, 13, and 17.5 eV for HSE06, corresponding to pronounced band transitions that coincide with points of inflection in the real part of the spectrum.

Inclusion of many-body effects within the $G_0W_0$ approximation results in a blue shift by $\sim 3$ eV (PBEsol) and 2 eV (HSE06) compared to the IP spectra, due to the increased band gaps within $G_0W_0$. This strong effect is attributed to the weak dielectric screening in MgO [13]. In Figs. 3b, d sharper features emerge in $\varepsilon_2$ with peaks at $\sim 11.8$, 14, and 19 eV (PBEsol), that are shifted to higher energies at $\sim 12.5$, 15, and 20.5 eV (HSE06). The real part of the spectrum in Figs. 3a, c exhibits weaker/smoothened features compared to experiment [4] (Fig. 3b, d). The macroscopic static electronic dielectric constant, $\varepsilon_\infty = \text{Re} \varepsilon(\omega = 0)$ obtained with PBEsol and HSE06 is presented in Table II. Within the IP approximation, $\varepsilon_\infty$ is overestimated for PBEsol (3.29) compared to the experimental value 2.94 [4], similar to previous results with GGA-PW91 (3.16) [17]. We also included the local field effects in the IP calculation and find that the dielectric constant decreases from 3.29 to 3.04 (PBEsol) and 2.76 to 2.57 (HSE06). A similar trend was observed in the work of Gajdoš et al. [42] for semiconductors as Si, SiC, AlP, GaAs, and for insulator as diamond (C). On the other hand, with the hybrid functional, $\varepsilon_\infty$ is underestimated (2.76). Upon including quasiparticle effects ($G_0W_0$), the values are substantially reduced to 2.78 (PBEsol) and 2.53 (HSE06).
FIG. 3. Optical spectrum of bulk MgO obtained with VASP: (a), (c) real part and (b), (d) imaginary part of the dielectric function for PBEsol and HSE06 as the starting functional, respectively. A Lorentzian broadening of 0.3 eV is employed for all the calculated spectra. The IP, IP+G₀W₀, and G₀W₀+BSE results are shown by brown solid, green dash-dotted, and red solid lines, respectively. Additionally, the experimental data from Exp. 1 [4] (black solid line), and Exp. 2 [23] (black dashed line) are displayed.

### TABLE II. Comparison of the macroscopic static electronic dielectric constant ε∞ in the IP approximation and after G₀W₀ and BSE with different DFT functionals.

| E_{xc} | IP | G₀W₀ | BSE | Experiment |
|--------|----|------|-----|------------|
| PBEsol | 3.29 | 2.78 | 3.08 | 2.94 [4] |
| HSE06  | 2.76 | 2.53 | 2.81 | 2.81 [23] |

2. Optical spectrum with excitonic corrections

Additional to the quasiparticle corrections, we consider the effects arising from electron-hole interaction by solving the Bethe-Salpeter equation. The calculations are performed with four occupied and five unoccupied bands which are sufficient to evaluate the optical spectrum up to 30 eV.

The inclusion of excitonic effects leads to a redistribution of the spectral weight to lower energies w.r.t. the G₀W₀ spectrum and the emergence of a sharp peak at the absorption onset. With PBEsol as the starting point in Fig. 3b, the agreement with experiment w.r.t. spectral shape is improved, but the onset of the imaginary part of the dielectric function is ∼0.7 eV lower than experiment [4, 23]. The prominent peaks are at ∼7.0 eV, 10 eV, 12.4 eV, and 16 eV. In the real part of the spectrum, the sign reversal at 12.8 eV indicates a plasmonic resonance.

On the other hand, using HSE06 as the starting functional, the real and imaginary part of the spectrum are in excellent agreement with experiment. The peak positions of the distinct features and the plasmonic resonance at 13.4 eV coincide with the experimental ones [23]. The four peaks of ε₂ at ∼8, 10.5, 13, and 17 eV are largely aligned with experiment, as shown in Figs. 3c and d. Further analysis of the origin of the peaks in reciprocal space and the real-space projection of the first exciton are provided in Section III B 3 and Section III D, respectively. The improved description w.r.t. the energetic positions and, to a lesser extent, intensity of the peaks can be attributed to the description of the ground state with a hybrid functional HSE06, the larger number of unoccupied bands considered in the BSE calculation and to performing BSE on top of G₀W₀. Furthermore, the agreement to experiment concerning the macroscopic static electronic dielectric constant ε∞ is improved after BSE to 3.08 (PBEsol) and 2.81 (HSE06), respectively (cf. Table II), also consistent with a previous value of 3.12 [17], where excitonic corrections were included using the KS eigenenergies and a scissor shift approach. We note that increasing the number of unoccupied bands to 9, leads to slightly higher values for ε∞ 3.16 (PBEsol) and 2.90 (HSE06), the latter being in excellent agreement with experiment. In particular, more empty states are necessary for the calculation of the real part of the dielectric function from the Kramers-Kronig relation. Due to the high computational cost and an enhanced memory
demand with more unoccupied bands, we proceed with five unoccupied bands for the further analysis.

Furthermore, for the binding energy of the first exciton we obtain 442 meV with PBEsol and 596 meV with HSE06. A similar value of 429 meV was obtained by Fuchs et al. [11] employing the KS eigenenergies (GGA) with a scissor shift of 2.98 eV and subsequently including excitonic corrections. The overestimation of the binding energy w.r.t experiment (80 meV [4]) may be attributed to the fact that the ionic contributions to the static screening is not considered [43, 44].

3. Analysis of spectral features in reciprocal space

In order to identify the origin of the most prominent peaks, we have performed calculations with the all-electron exciting code. The real and imaginary part of the dielectric function for the $G_0W_0$+BSE with PBEsol as the DFT functional and similar parameters (four occupied and five unoccupied bands) are plotted in Figs. 4a, b, and show good agreement with experiment as well as the VASP result w.r.t. the energetic positions of the peaks (a comparison of the spectra obtained with the two codes is provided in Appendix A and Fig. 8). The PBEsol band gap is 4.60 eV at the KS level and increases to 7.25 eV after quasiparticle corrections with $G_0W_0$ are included. The most prominent peaks are marked in Fig. 4b and the corresponding e-h contributions are studied in Figs. 4c-f. We recall that the Bethe-Salpeter equation represents an eigenvalue problem for an effective two-particle Hamiltonian [37, 45]:

$$\sum_{v'c'} H_{vck,v'c'k'} A^\lambda_{vck} A^\lambda_{v'c'k'} = E^\lambda A^\lambda_{vck}. \quad (1)$$

where $E^\lambda$ are the transition energies and $A^\lambda_{vck}$ are the corresponding states in terms of $v k \rightarrow c k$ transitions. The e-h coupling coefficients for a particular transition displayed as circles in Figs. 4c-f are calculated from the BSE eigenvector $A^\lambda$ as:

$$w^\lambda_{vck} = \sum_c |A^\lambda_{vck}|^2, \quad w^\lambda_{v'c'k'} = \sum_v |A^\lambda_{v'c'k'}|^2. \quad (2)$$

The first exciton at 6.82 eV has a binding energy of 435 meV, close to the value obtained with VASP, as discussed in the previous section. This bound exciton contributes to the shoulder at the onset of the spectrum. The interband transitions responsible for the exciton and its real-space distribution are discussed in detail in Section III D. In Fig. 4 a, the green line marks the fundamental band gap, below which the bound excitons lie.

The first peak at 7.3 eV (cf. Fig. 4c) arises due to transitions from the top of the valence band (VB) to the bottom of the conduction band (CB) around the $\Gamma$-point in reciprocal space. A comparison with the site and orbital-projected DOS (Fig. 1) and band structure (Fig. 2) reveals a mixed O 3s, 3p, and Mg 3s character. The second peak at 9.4 eV involves interband transitions from the topmost VB to the lowest CB along $L - \Gamma - X$ and $\Gamma - K$. The CB is more dispersive along $L - \Gamma - X$ and $\Gamma - K$. The final peak at 12.2 eV, plotted in Fig. 4f, results from transitions from the top of the VB to the higher-lying CB around X as well as along $K - \Gamma$. In this energy range, the CB consists of O 3p and Mg 3s and 3d_{xy}, d_{xz} states along $\Gamma - X$ and $K - \Gamma$.

The influence of lattice screening on the optical spectrum is a topic of current research and so far there is no established framework to treat the exciton-phonon coupling that renormalizes the absorption spectra. Such effects should be assessed in future work.

C. X-ray absorption spectra

We now turn to the x-ray absorption spectra of the O and Mg K-edge of bulk MgO calculated with the exciting code. The ground state calculations were performed with the PBEsol exchange-correlation functional and the quasiparticle corrections were included with the single-step $G_0W_0$. Finally, the excitonic corrections were accounted for by solving BSE.

1. O K-edge

The theoretical XAS spectrum of the O K-edge is plotted in Fig. 5d together with the experimental spectrum from Luches et al. [25], who performed x-ray absorption measurements on MgO films of varying thickness grown epitaxially on Ag(001) as well as on polycrystalline bulk samples. The $G_0W_0$+BSE spectrum is characterized by six prominent peaks with high oscillator strength (cf. Fig. 5a). Their origin in terms of transitions to the conduction bands is visualized in Fig. 5b-g. We find that for the BSE calculation, a total of eight unoccupied bands are sufficient to obtain agreement with experiment and converge the oscillator strengths in the energy interval up to 30 eV.

While the spectrum within the independent quasiparticle aproximation (IQPA) obtained after the $G_0W_0$ correction captures the four peak-feature, a very good agreement to experiment concerning the spectral shape and the relative positions of the three prominent peaks at $\sim 537, 546,$ and 557 eV is obtained only after the $G_0W_0$+BSE corrections. The spectrum is also consistent with earlier work of Rehr et al. [20] using FSR and BSE. The reduced intensity of the third peak in the $G_0W_0$+BSE spectrum can be attributed to the limited number of unoccupied bands considered in the calculation. Typically, the GW approximation is not widely explored for core-level states, only recently there are first promising reports for its application to molecular 1s lev-
FIG. 4. Optical spectrum with PBEsol including many-body corrections calculated with the exciting code: (a) real and (b) imaginary part of the dielectric function. A Lorentzian broadening 0.3 eV is employed for the calculated spectrum for the $G_0W_0$+BSE corrections (red line) and the red vertical bars represent the oscillator strength (arb. units). The direct band gap at 7.26 eV is marked by a vertical green line. Experimental spectra from Roelssler et al. [4] (black solid line) and Bortz et al. [23] (black dashed line) are shown for comparison. (c–f) electron-hole coupling coefficients represented as circles in reciprocal space for the peaks at different energies marked in (b), where the size of the circle is proportional to the magnitude of the e-h contribution.

 els [46]. In our calculations we do not correct the core energies obtained from DFT. Thus we shift the BSE spectrum to align with the experiment, as done in earlier works [22, 47]. For the O K-edge a shift of 34.4 eV is applied to the $G_0W_0$+BSE spectrum to align the first peak with experiment. The same shift is also applied to the IQPA spectrum.

The green line in Fig. 5 a marks the direct band gap and the states below it correspond to bound excitons. The first bound exciton at the O K-edge is found at 534.5 eV with a binding energy of 690 meV, its real-space distribution is discussed in Section III D. This value is comparable to previous results for other oxides, e.g. 0.5 eV was reported for $\beta$-Ga$_2$O$_3$ [48], and 285 meV, 345 meV, and 323 meV for the $\alpha$-, $\beta$-, and $\epsilon$ phase of Ga$_2$O$_3$ [49], respectively. Six prominent features in the XAS spectrum with high oscillator strength are marked and their origin is analyzed further in Figs. 5b-g. Transitions at the onset of the spectrum at 535.3 eV are localized around $\Gamma$ at the bottom of the CB (Fig. 5b) and comprise predominantly O 3p character hybridized with O 3s (cf. Figs. 2a-c), and Mg 3s character (cf. Fig. 2d). The second peak at 536.9 eV also arises from transitions to the lowest CB, but is more dispersive along $L - \Gamma - X$ and $K - \Gamma$. The subsequent peak at 537.7 eV stems from transitions to the lowest CB, but is localized midway along the $L - \Gamma$ with some contribution along $K - \Gamma$ and has hybridized O 3s, 3p, and Mg 3s character. Furthermore, the peak at 539.5 eV results from transitions to the second lowest unoccupied band localized at X and dispersive along $K - \Gamma$ with Mg 3$d_{xz}$ (cf. Fig. 2f) as well as O 3p character. Transitions to higher unoccupied bands around W and $\Gamma$ with mixed O 3p and 3d and Mg 3p, $t_{2g}$ character result in a peak at 546.5 eV. The final peak at 557.2 eV arises from transitions to CB at energies above 25 eV with O 3p and Mg 3p, $e_g$ contributions along $X - W - K - \Gamma$.

2. Mg K-edge

Fig. 6a displays the Mg K-edge from the $G_0W_0$+BSE calculation and the experimental spectrum from Luches et al. [25]. The experimental spectrum has four prominent peaks at 1308.3, 1314.4, and 1316.2 eV, followed by a broader peak at 1326.6 eV, with a noticeable difference in peak intensities for normal and grazing incidence of the MgO film on Ag(001) and for the polycrystalline sample. While the IQPA spectrum for the O K-edge shows
FIG. 5. XAS spectrum of the O K-edge using $G_0W_0$+BSE calculated with the $\textbf{exciting}$ code: (a) calculated absorption spectra with $G_0W_0$+BSE (red line) and within the independent quasiparticle approximation (IQPA, brown shaded area) are compared with experimental spectra from Luches $et$ $al.$ [25] (black line). A shift of 34.4 eV was applied to the calculated spectra to align to the first peak of the experiment and a Lorentzian broadening of 0.55 eV is adopted to mimic the excitation lifetime. The green line at 535.2 eV marks the direct band gap. The red vertical bars represent the oscillator strength (arb. units). (b-g) excitonic contributions to the final states in the CB of the peaks marked in (a).

overall agreement with the $G_0W_0$+BSE result, for the Mg K-edge the IQPA spectrum fails to describe the general features of the experimental spectrum. On the other hand, including the core-hole - electron interaction leads to a large redistribution of the spectral weight, accompanied by the emergence of a high intensity peak at the onset of the BSE spectrum. Overall, the $G_0W_0$+BSE Mg K-edge is in very good agreement with the experimental spectrum of [25] and with previous BSE and FSR calculations [20] concerning peak positions and relative intensity. Similar to the O K-edge, we applied a shift of 58.8 eV to the $G_0W_0$+BSE spectrum to align it to the first peak in the experimental spectrum and the same shift is applied to the IQPA spectrum.

The green line in Fig. 6a denotes the presence of bound excitons below this energy, the first bound exciton being at 1305.81 eV with a binding energy of 760 meV. Ten prominent peaks with high oscillator strength are marked in the spectrum which are analyzed further in Figs. 6b-k. The first peak at 1307.4 eV arises from transitions to the bottom of CB with Mg 3p character, hybridized with Mg 3s states (cf. Figs. 2a,b). The second peak at 1308.2 eV comprises transitions along the L − $\Gamma$ − X with Mg 3p character and along K − $\Gamma$ with mixed Mg 3s and 3p character. The third peak at 1310.1 eV includes transitions to the lowest CB concentrated halfway between $\Gamma$ − X with hybridized Mg 3s and O 3s and 3p character (cf. Figs. 2a,b). Moreover, the peaks at 1313.8, 1315.6, and 1316.7 eV arise from transitions to higher energy CB (>10 eV) and are dispersive along the whole k-path with hybridized O 3p and Mg 3s and 3p as well as Mg 3d$_{xz}$ character (cf. Figs. 2d-f). The peaks at 1323.6, 1325.7, 1327.6, and 1329.5 eV stem from the transitions to the unoccupied bands with $E > 20$ eV predominantly along X − W − K with prevailing hybridized Mg 3p and $e_g$ character.

D. Real-space projection of the first exciton

The real-space wavefunction of the excited electron for a given exciton can be obtained from the BSE eigenvectors $A^\lambda$ as:

$$\Psi^\lambda(r_h, r_e) = \sum_{vck} A^\lambda_{vck} \psi^*_{ck}(r_h) \psi_{ck}(r_e).$$

For more details see Ref. [37, 47] and references therein. For the analysis we fixed the hole slightly off the oxygen
FIG. 6. XAS spectrum of Mg K-edge including $G_0W_0+$BSE corrections calculated with the exciting code: (a) calculated absorption spectra with $G_0W_0+$BSE (red line) and within IQPA (brown shaded area) are compared with experimental spectra from Luches et al. [25] on a MgO film on Ag(001), grazing/normal incidence of photon beam (black dashed-dotted/solid line); polycrystalline MgO (black dashed line). A shift of 58.8 eV was applied to the calculated spectra to achieve coincidence with the first peak of the experiment and a Lorentzian broadening of 0.55 eV is adopted for the theoretical curve to mimic the excitation lifetime. The vertical green line at 1306.6 eV marks the direct band gap. The red vertical bars represent the oscillator strength (arb. units). (b-k) excitonic contributions to the final states in the CB of the peaks marked in (a).

Position (0.52,0.52,0.52) and plotted the electronic part of the wavefunction in real-space for the first exciton of the optical and the O K-edge XAS spectrum in Fig. 7.

The first bound exciton of the optical spectrum (Fig. 7a) consists of transition from the valence band maximum (VBM) to the conduction band minimum (CBM) that are strongly localized around $\Gamma$. Since the excited electron is distributed solely over the lowest, highly dispersive conduction band, the bound exciton was previously described in the Wannier-Mott two-band model by Fuchs et al. [11]. In Fig. 7c we display a cut along the (56i) plane through the center of the spread of the wave function near the fixed position of the hole, that shows that the exciton is delocalized over several unit cells which supports the Wannier-Mott character. Moreover the intensity of the spread has a maximum at the oxygen sites and is weaker at the Mg sites. The reciprocal space projection in conjunction with the orbitally projected band structure (cf. Fig. 2) shows a main contribution of hybridized O 3$s$ and Mg 3$s$ states at the CBM.

For comparison, we have also analyzed the real space
FIG. 7. Analysis of the first exciton in the optical spectrum (a) and O K-edge XAS (b) in reciprocal space. The lower panels show the density associated with the electronic part of the excitonic wavefunctions for a selected cross section in real space: In (c) along (561) for the optical excitation shown in (a) and (d) along (516) for the O K-edge XAS in (b). The color code visualizes the spatial extension of the wave functions: Blue colors refer to vanishing or low densities, orange to red colors to elevated densities. The hole is fixed near the oxygen (fractional coordinate: 0.52, 0.52, 0.52) and is marked by a white cross.

projection of the first exciton in the O K-edge XAS spectrum. As shown in Fig. 7b this exciton involves transitions to the CBM, but is more dispersive in reciprocal space along \( L - \Gamma - X \) and \( K - \Gamma \). This goes hand in hand with a stronger localization in real space, visible from the real space projection in Fig. 7d along the (516) plane that exhibits a significant decrease in the spread of the wavefunction. Compared to the exciton of the optical spectrum, here the spread is confined to two to three unit cells only. The 2D cut through the center of the wavefunction spread also illustrates the orbital contributions with \( s \) and \( p \) character near the O sites, whereas the contributions around the Mg sites have \( s \)-like character. This can be attributed to the strong hybridization of the O 3\( s \), 3\( p \), and Mg 3\( s \) states around the CBM, discussed above.

IV. SUMMARY

We have provided a comprehensive study of the optical and x-ray absorption spectra of bulk MgO with the VASP and exciting codes. The results indicate that the quasiparticle, and in particular excitonic effects are crucial to describe the spectra, concerning peak positions and to a lesser extent intensity.

For the optical spectrum, the effect of two different functionals (GGA-PBEsol and the hybrid HSE06) are studied: an excellent agreement with the experiment is obtained with HSE06 w.r.t. the energetic positions of the peaks. Analysis of the electron-hole coupling coefficients in reciprocal space allows us to identify the valence to conduction band transitions contributing to the peaks in the spectrum. In particular, the peak at 7.3 eV arises due to transitions localized around \( \Gamma \) from the top of the VB to the bottom of the CB with mixed O 3\( s \), 3\( p \), and Mg 3\( s \) character, followed by a peak at 9.4 eV stemming from similar interband transitions but along \( L - \Gamma - X \) and...
The real space projection of the electronic part of the wavefunction of the first exciton in the optical spectrum shows it has a delocalized Wannier-Mott character, consistent with previous studies in reciprocal space [11]. On the other hand, the wavefunction of the first exciton in the O K-edge spectrum is stronger localized and spreads up to only three unit cells. We believe that our detailed analysis of the optical and x-ray excitations in this paradigmatic oxide material regarding their orbital character and extension in real and reciprocal space based on state-of-the-art many-body approaches serves as an important benchmark and provides useful background information for the interpretation of experimental data both from static but also time-dependent investigations.

ACKNOWLEDGMENTS

We thank Caterina Cocchi, André Schleife, Heiko Wende, Andrea Eschenlohr, Katharina Ollefs, Nico Rothienbach, and Okan Köksal for fruitful discussions. We wish to acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) within collaborative research center CRC1242 (project number 278162697, subproject C02) and computational time at the Center for Computational Sciences and Simulation of the University of Duisburg-Essen on the supercomputer magniUDE (DFG grants INST 20876/209-1 FUGG, INST 20876/243-1 FUGG). C. V. and C. D. appreciate funding from the Leibniz-ScienceCampus GraFOx.

Appendix A: Comparison of the optical spectrum calculated with exciting and VASP

The optical spectra obtained with exciting and VASP with the same exchange-correlation functional (PBEsol) in Fig. 8 show very good agreement in the overall shape and peak positions with some smaller differences in peak heights.

FIG. 8. Comparison of the $G_0W_0$-BSE spectrum calculated with PBEsol as the starting functional with exciting (red solid line) and VASP (blue solid line). The spectra are compared with the experiments of Roessler et al. [4] (black dashed line) and Bortz et al. [23] (black dashed line). A Lorentzian broadening of 0.3 eV is employed for the theory spectra.

Appendix B: DFT+model-BSE (mBSE)

Fuchs et al. [11] have pointed out the importance of using a dense $k$-mesh for BSE in order to obtain convergence of the optical spectrum in the lower energy range. However, this goes hand in hand with a high computation cost in the $G_0W_0$ calculation. One way to circumvent this is to perform a model BSE calculation directly using the DFT wave functions and considering only the required number of bands which cover the energy range of interest [11]. The omission of the $G_0W_0$ step allows us to use a higher $k$-mesh and thus improve the convergence. Here, we discuss the result obtained by using a model for the static screening with parameters fitted to the screened Coulomb kernel diagonal values obtained from $G_0W_0$ calculation, a detailed description can be found in Ref. [11, 24, 50, 51] and was previously used in Ref. [24, 50]. Good agreement between mBSE and the full BSE ($G_0W_0$+BSE) is recently obtained for bulk SrTiO$_3$ [41].

In our study, mBSE is performed on a $21 \times 21 \times 21 k$-mesh with a range separation parameter $\lambda = 1.44 \text{ Å}^{-1}$, ion-clamped static dielectric function $\epsilon_\infty^{-1} = 0.38974$, and a scissor shift of 1.95 eV, corresponding to the difference between the KS energies obtained with HSE06 and the quasiparticle band gap. In Fig. 9 the spectrum from mBSE and full BSE obtained with HSE06 as the starting functional on a $k$-mesh of $15 \times 15 \times 15$ are displayed. Overall, very good agreement is obtained. In particular,
in the energy range of 7 – 11 eV we even observe a better agreement with experiment for mBSE when compared with full BSE associated with the increase in k-point density. For energies higher than 11 eV, the positions of the peaks are also well reproduced with the mBSE approach with slight increase in the intensity when compared with the full BSE spectrum. The good agreement between the mBSE and full BSE spectra is attributed to the fact that the electronic structure does not change significantly from DFT to \( G_0 W_0 \) (cf. Fig. 1), the prevailing effect being a rigid shift of the conduction band. The binding energy of the first exciton from mBSE is 610.8 meV.
