(Dated: July 11, 2018)

We propose theoretically an effective scheme for braiding Majorana bound states by manipulating the point potential. The vortex pinning effect is carefully elucidated. This effect may be used to control the vortices and Majorana bound states in topological superconductors. The exchange of two vortices induced by moving the potentials is simulated numerically. The zero-energy state in the vortex core is robust with respect to the strength of the potential. The Majorana bound states in a pinned vortex are identified numerically.

I. INTRODUCTION

Topological superconductors have been studied intensively because of their exotic properties [1]. They are characterized by a bulk superconducting gap and topologically protected gapless states at the system edges, which are subject to the excitation of Majorana bound states (MBSs). In the past, the realization of MBSs in various topological superconducting systems has attracted broad interest [2–17]. Theoretically, a straightforward mechanism is that MBSs appear at the system edges and vortex cores of a $p + ip$ superconductor [2]. However, searching for a superconducting material with $p$-wave pairing symmetry is a great challenge. Therefore, many more realistic models have also been proposed [3–7]. One well-known proposal is that a $p + ip$ superconductor is equivalent to a system with an $s$-wave superconductor coupled to a topological insulator. In the presence of a magnetic field, MBSs will be excited in the vortex cores [3]. Another promising proposal is that MBSs can be realized in a sandwich system that includes $s$-wave pairing, spin-orbital interaction and a Zeeman field. Then, by tuning the Fermi level, this system can also be made equivalent to a $p+ip$ superconductor [4–7]. The two proposals introduced above have both been realized experimentally, and possible signatures of MBSs have been reported based on the zero-bias peak in the differential tunneling conductance measured in scanning tunneling microscopy experiments [3,13].

One of the most important features of MBSs is that they usually obey non-Abelian statistics [15]. This feature is of fundamental interest, and a direct experimental demonstration of non-Abelian statistics may provide definite evidence of the existence of MBSs. Moreover, this property has potential applications in topological quantum computations. However, it is rather difficult to find an experimental platform with which to realize the braiding of MBSs and demonstrate their non-Abelian statistics. Although there have been many theoretical proposals [14–27], to date, this remains an open question. Very recently, it was reported that the exchange of Majorana zero modes can be simulated using a photonic system [28, 29]. However, there has still been no experimental realization of the manipulation MBSs to demonstrate their non-Abelian statistics in topological superconductors.

The interaction between a vortex and a point potential has previously attracted broad interest [30–33]. It has been demonstrated numerically that the center of a vortex may be attracted and pinned by a point potential. Such a pinning effect is of both theoretical and practical interest. Another important issue is the interplay between the vortex bound states and the potentials. However, numerically different results have been reported in different families of superconductors [31,32]. In topological superconductors, the pinning effect induced by a local potential and its possible applications have not previously been explored. In fact, this possible pinning effect may offer a potential method of controlling vortices. In particular, it has been verified theoretically that the zero energy bound states are topologically protected and that they are not affected by local potentials [34,39]. If the zero-energy bound states are subjected to the MBS excitation, then the pinning effect may provide an effective means of manipulating the MBSs in topological superconductor.
The braiding of the MBSs may be realized by manipulating the potentials.

In this paper, motivated by the above considerations, we study theoretically the effect of a point potential on a vortex state using the self-consistent Bogoliubov-de Gennes (BdG) technique. An effective controllable point potential can be produced by means of atomic force microscopy \cite{49}. As shown in Fig. 1, we consider an atomic-scale tip mounted on a movable device. The potential originates from the interaction between atoms at the front of the tip and the quasiparticles in the sample. We propose that the Coulomb interaction may produce a suitable potential. The strength of the potential can be well controlled, and due to the screening effect, the Coulomb potential is rather localized and may be treated as a point potential. Starting from an effective model describing topological superconductors \cite{4 7}, the vortex pinning effect and the critical pinning distance are investigated, to seek an effective method of controlling and manipulating the MBSs. The exchange of two vortices induced by slowly moving two point potentials is simulated. We also check numerically that the zero mode is robust against the potentials. Meanwhile, it is clearly verified that the zero mode is indeed subject to two separate MBSs.

The rest of the paper is organized as follows. In Sec. II, we introduce the model and derive the formalism. In Sec. III, we report numerical calculations and discuss the obtained results. Finally, we present a brief summary in Sec. IV.

II. MODEL AND HAMILTONIAN

Following Refs. \cite{4 7}, an effective theoretical model that describes a topological superconductor includes a hopping term, spin-orbital coupling, a Zeeman field, and an s-wave superconducting pairing term. Considering the terms listed above, our starting model is expressed as

\begin{equation}
H = H_t + H_{SO} + H_{SC}.
\end{equation}

Here, \(H_t\) includes the hopping term, the chemical potential term, the Zeeman field, and an additional point potential term; it is expressed as,

\begin{equation}
H_t = -\sum_{\langle ij \rangle} t_0 \Psi_{ij} (c_i^\dagger c_j + h.c.) + \sum_{\sigma} (\sigma h - \mu) c_i^\dagger \sigma c_i^\sigma + \sum_{\sigma} V_i c_i^\dagger \sigma c_{i0}^\sigma.
\end{equation}

(\(\langle ij \rangle\)) represents the nearest-neighbor sites. \(t_0\) is the nearest-neighbor hopping constant. In the presence of a magnetic field, we have \(\Psi_{ij} = \exp(i\pi/\phi_0) \int_{R_0} A(r) dr\), where \(\phi_0\) is the superconducting flux quantum and \(A = (-B y, 0, 0)\) is the vector potential in the Landau gauge. \(h\) is the Zeeman field. The sign \(\sigma\) is “+” for the spin-up state and “−” for the spin-down state. \(\mu\) is the chemical potential. We consider a point potential at site \(i_0\) with a strength of \(V_i\).

\(H_{SO}\) is the spin-orbital interaction, expressed as

\begin{equation}
H_{SO} = \sum_i (i\lambda \Phi_{ij} c_{ij}^\dagger c_{i+\pi\downarrow} + i\lambda \Phi_{ij} c_{ij}^\dagger c_{i+\pi\uparrow} + h.c.) + \lambda \Phi_{ij} c_{ij}^\dagger c_{i+\pi\downarrow} - \lambda \Phi_{ij} c_{ij}^\dagger c_{i+\pi\uparrow} + h.c.,
\end{equation}

where \(\lambda\) is the spin-orbital coupling strength.

\(H_{SC}\) is the superconducting pairing term, expressed as

\begin{equation}
H_{SC} = \sum_{\langle ij \rangle} (\Delta_{ij} c_i^\dagger \sigma c_{j\sigma} + h.c.).
\end{equation}

Here, \(\Delta_{ij}\) is the on-site pairing order parameter, that originates from an on-site attractive interaction.

The above Hamiltonian can be diagonalized by solving the BdG equations self-consistently:

\begin{equation}
\sum_j \begin{pmatrix} H_{ij}^{\uparrow\uparrow} & H_{ij}^{\uparrow\downarrow} & \Delta_{ij} & 0 \\ H_{ij}^{\downarrow\uparrow} & H_{ij}^{\downarrow\downarrow} & 0 & -\Delta_{ij} \\ -\Delta_{ij}^* & 0 & -H_{ij}^{\downarrow\downarrow} & -H_{ij}^{\uparrow\uparrow} \\ 0 & -\Delta_{ij}^* & -H_{ij}^{\uparrow\downarrow} & -H_{ij}^{\uparrow\uparrow} \end{pmatrix} \begin{pmatrix} \Psi_j^\eta \\ \Psi_{j+1}^\eta \\ \Psi_{j-1}^\eta \\ \Psi_j^{\eta*} \end{pmatrix} = E_\eta \begin{pmatrix} \Psi_j^\eta \\ \Psi_{j+1}^\eta \\ \Psi_{j-1}^\eta \\ \Psi_j^{\eta*} \end{pmatrix},
\end{equation}

where \(\Psi_j^\eta = (u_j^\eta, u_{j+1}^\eta, u_{j-1}^\eta, v_j^\eta)^T\), \(H_{ij\sigma\sigma}\) and \(H_{ij\sigma\bar{\sigma}}\) (\(\sigma \neq \bar{\sigma}\)) are obtained from \(H_t\) and \(H_{SO}\), respectively.

The order parameters \(\Delta_{ij}\) are calculated as follows:

\begin{equation}
\Delta_{ij} = V/2 \sum_{\eta} (u_j^\eta, u_{j+1}^\eta, u_{j-1}^\eta, v_j^\eta)^T \tanh(E_\eta/2K_BT),
\end{equation}

where \(V\) is the pairing strength.

The BdG equations are solved self-consistently as follows. First, we input a set of initial order parameters \(\Delta_{ij}\) and diagonalize the Hamiltonian matrix. Second, we use the obtained eigenfunctions and eigenvalues to calculate the new order parameters as expressed in Eq.(6). This procedure is repeated with the updated order parameters until the convergence criterion is satisfied.

In the results reported below, we use the lattice constant \(a\) and the nearest-neighbor hopping constant \(t_0\) as the units of length and energy, respectively. Without loss of generality, the other parameters are set to \(\mu = -4\), \(h = 0.6\), and \(V = 5\), respectively. Then, the Hamiltonian given in Eq.(1) is an effective model that describes the corresponding topological superconductor. The superconducting gap is calculated self-consistently on the \(N = 48 \times 48\) lattice with periodic boundary conditions. The magnetic field \(B\) is chosen to be \(B = 2\phi_0/(Na^2)\). Under these conditions, two vortices should exist in the system. We have checked numerically that our main results are not qualitatively different for different input parameters.

III. RESULTS AND DISCUSSIONS

We first investigate the pinning effect and the pinning distance. The spatial variations of the superconducting pairing order parameter without an additional point potential and with a single potential at different sites are
As shown, \( R \) potentials, approximately six times the lattice constant for strong for an attractive potential and \( V \) as a function of the potential potential strength where \( h \). In our present model, a critical Zeeman field \( c \) exists, centered at the sites (12, 36) and (36, 12). In this step, we use \( V_i = 0 \) as the input parameters. The critical pinning distance \( R_c \) does not change as \( h \) crosses \( h_c \). Thus, the vortex pinning effect described above is not a unique property of topological superconductors. Indeed, similar effects have been previously reported in other families of superconductors [30–33]. However, we emphasize here that for topological superconductors, the vortex pinning effect may be particularly interesting and practical useful. As presented in Fig. 1, when the potential site is far away from the center of a vortex, it does not affect that vortex. However, if the point potential can be well controlled and is moved slowly away from the vortex center, we expect that the vortex will be dragged along with the potential. If the vortex density is sufficiently low that the interaction between vortices is negligibly small, then, in principle, the vortex may be dragged to any site in the system. Because the vortices in topological superconductors are usually associated with MBS excitation, this dragging effect may be used to achieve the braiding of MBSs.

We attempt to manipulate the vortices by moving the potentials in accordance with the above assumption. As the first step, we assume that a single potential \( (V_i = 10) \) exists at the center of a vortex \( r = R_0 \) \([R_0 = (12, 36)]\). The site-dependent order parameters can be obtained by solving the BdG equations. We then move the potential from \( R_0 \) to its neighbor site \( R_1 \). In this step, we use the self-consistent results for \( r = R_0 \) as the initial input parameters to calculate the updated order parameters for \( r = R_1 \). Then, the potential is moved to \( R_2 \), and the self-consistent results for \( r = R_1 \) are used as the new input parameters. In this way, we move the vortex from the site \( R_0 = (12, 36) \) to the site \( R_f = (28, 36) \) by slowly changing the point potential. The intensity plot of the order parameters after the potential has been moved to the site \( R_f \) is presented in Fig. 4(a). Note that here, the distance between \( R_f \) and \( R_0 \) reaches sixteen times lattice constants, much larger than the critical pinning distance.

**FIG. 3**: The critical pinning distance \( R_c \) as a function of the potential strength \( V_i \).
Our results indicate that the vortex can indeed be well controlled if we move the potential sufficiently slowly.

We now simulate the exchange of the two vortices, which is achieved by manipulating two point potentials. As displayed in Fig. 4(b), initially, two pinned vortices exist at the sites (12, 36) (vortex A) and (36, 12) (vortex B). Then, the potentials are moved slowly along the directions of the corresponding arrows. As the positions of the potentials move, the previous self-consistent results are taken as the new initial input parameters. Several intermediate results are displayed in Figs. 4(c-e). The final result is presented in Fig. 4(f), where the vortices A and B have moved to the sites (36, 12) and (12, 36), respectively. Therefore, using this method, we can successfully exchange the two vortices.

We have demonstrated that vortices can be well controlled by means of the manipulation of point potentials. However, one essential question is whether the MBSs will survive for pinned vortices. According to previous theoretical calculations, the zero-energy bound states should be robust with respect to a point potential. However, the zero-energy bound states are not necessarily subject to the MBS excitation. Therefore, it is still important to check numerically whether the MBSs are robust when a vortex is pinned by a point potential. We consider one point potential located at the site (12,36) ($V_1 = 10$). The eigenvalues obtained by diagonalizing the Hamiltonian are plotted in Fig. 5(a). Two zero-energy eigenvalues are clearly seen from the numerical results, protected by a minigap of approximately 0.1. The existence of topologically protected zero-energy states usually indicates MBS excitation. We will discuss this issue further in relation to the results presented below.

For the Hamiltonian with the superconducting pairing term, the eigenvalues $E$ and $-E$ always appear in pairs due to particle-hole symmetry, where the corresponding eigenvectors are denoted by $C$ and $C^\dagger$, respectively. For a zero energy particle ($E = 0$), $C$ and $C^\dagger$ are obviously degenerate. Therefore, their superpositions are also eigenvectors of the Hamiltonian. Then, one can obtain two Majorana particles, $\gamma_{1,2}$, from the particle operators $C$ and $C^\dagger$, expressed as $\gamma_1 = (C + C^\dagger)/\sqrt{2}$ and $\gamma_2 = i(C^\dagger - C)/\sqrt{2}$. Here, $C$ and $C^\dagger$ are obtained numerically from the eigenvectors corresponding to the zero-energy eigenvalues. Thus, the existence of MBSs can be studied and identified numerically. The spatial distributions of the two MBSs are plotted in panels (b) and (c).

Finally, we would like to discuss the practical feasibility of our scheme. First, it is important to clarify whether the results are qualitatively the same when a local potential of a finite size is considered. We have checked numerically that the zero-energy states and the MBSs are robust to local potentials of larger scale. Moreover, the critical pinning distance $R_c$ increases significantly when offsite potentials are added. Therefore, in fact, the MBSs are easier to control in a real system, in which the actual potential may cover several sites. Second, our scheme requires the vortex density to be low enough that the dragging force will dominate over the interaction between vortices and that other vortices will not be affected when one vortex is dragged by a potential. The vortex density is determined by the magnetic field strength $B$ and can be calculated theoretically. Under the assumption that the lattice constant $a$ is about 3Å, the magnetic field $B$ is estimated to be approximately 20T in our present work. This is much larger than the experimental value. In a real system, the vortex lattice can survive for a rather low magnetic field (0.02T) [41]. With this field strength the distance between two neighboring vortices is rather large (approximately 3460Å). Thus, we can safely conclude that in a real system, the vortex density can be
IV. SUMMARY

In summary, we have studied theoretically the effect of a point potential on the vortex states in topological superconductors. The center of a vortex is dragged to the potential when the potential is close to the vortex. This pinning effect may be used to control vortices. We simulated the exchange of two vortices induced by slowly moving two point potentials. The zero-energy states and the MBS excitation for a pinned vortex were identified numerically. Therefore, we have presented an effective scheme for the braiding of MBSs.
