Abstract

We present ALMA Band 7 data of the [C II] $\lambda 157.74$ $\mu$m emission line and underlying far-IR (FIR) continuum for 12 luminous quasars at $z \approx 4.8$ powered by fast-growing supermassive black holes (SMBHs). Our total sample consists of 18 quasars, 12 of which are presented here for the first time. The new sources consist of six Herschel/SPIRE-detected systems, which we define as “FIR-bright” sources, and six Herschel/SPIRE-undetected systems, which we define as “FIR-faint” sources. We determine dust masses for the quasars hosts of $M_{\text{dust}} \leq 0.2–25.0 \times 10^{9} M_{\odot}$, implying interstellar medium gas masses comparable to the dynamical masses derived from the [C II] kinematics. It is found that, on average, the Mg II line is blueshifted by $\sim 500$ km s$^{-1}$ with respect to the [C II] emission line, which is also observed when complementing our observations with data from the literature. We find that all of our FIR-bright subsample and most of the FIR-faint objects lie above the main sequence of star-forming galaxies at $z \sim 5$. We detect companion submillimeter galaxies for two sources, both FIR-faint, with a range of projected distances of $\sim 20–60$ kpc and typical velocity shifts of $|\Delta v| \lesssim 200$ km s$^{-1}$ from the quasar hosts. Of our total sample of 18 quasars, 5/18 are found to have dust-obscured star-forming companions.

1. Introduction

Most galaxies are believed to host a supermassive black hole (SMBH) at their center (Kormendy & Ho 2013). Both active galactic nuclei (AGNs) and star formation (SF) luminosity functions are found to peak at $z \sim 2$, declining toward lower redshifts (Aird et al. 2015; Fiore et al. 2017). Hence, a coordinated growth of SMBHs and the stellar mass of their hosts has been proposed. These SMBHs can grow through accretion during an AGN phase (Salpeter 1964), while the growth of their stellar mass can be measured through their SF. It is commonly believed that accretion onto SMBHs and intense starburst activity occur nearly simultaneously, with both processes pulling from a shared reservoir of cold gas. These reservoirs of cold gas are commonly proposed to be fed by major mergers (Di Matteo et al. 2005; Hopkins et al. 2006; Somerville et al. 2008).

Testing these scenarios observationally has proven to be extremely challenging, since it requires one to characterize accreting SMBHs and their hosts for well-defined samples. The AGN-related emission dominates over most of the optical-to-near-IR (NIR) spectral regime, significantly limiting the prospects of determining the host properties. The best strategy is to observe these systems in the far-IR (FIR), where dust heated by the SF dominates the continuum emission and interstellar emission lines allow us to determine the host kinematics. For high-$z$ sources, this can be readily achieved through Atacama Large Millimeter/submillimeter Array (ALMA) submillimeter observations.

Following the work in our pilot sample of Trakhtenbrot et al. (2017, hereafter T17), we continue to probe the connection between SMBHs and their host galaxies using an optically selected, flux-limited sample of the most luminous quasars at $z \sim 4.8$. These fast-growing SMBHs should also be experiencing fast stellar growth, as seen in high-$\lambda_{\text{AGN}}$ systems studied at $z \sim 1–3$ (Netzer et al. 2007; Rosario et al. 2012; Lutz 2014).

Throughout this work, we assume a cosmological model with $\Omega_{\Lambda} = 0.7$, $\Omega_{M} = 0.3$, and $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, which provides an angular scale of about 6.47 kpc arcsec$^{-1}$ at $z = 4.8$, the typical redshift of our sources. In Section 2 we describe our data sample, observations, and methods of data reduction and analysis. In Section 3 we present results on the host galaxy properties of our sample and compare the occurrence of companions to other ALMA samples. Finally, in Section 4 we summarize the results and findings of our work. We further assume the stellar initial mass function (IMF) of Chabrier (2003).

2. Sample, ALMA Observations, and Data Analysis

2.1. Previous Observations and Sample Properties

Our original sample is a selection of the 38 brightest ($L_{\text{bol}} \sim 3–23 \times 10^{46}$ erg s$^{-1}$) unobscured quasars from the sixth data release of the Sloan Digital Sky Survey (SDSS DR6; York et al. 2000; Adelman-McCarthy et al. 2008) at redshifts $z \sim 4.65–4.92$. This redshift range, which we will often refer to as $z \approx 4.8$, was selected to allow follow-up observations of the Mg II $\lambda 2798$ emission line and nearby 3000 Å continuum luminosity. Observations of Mg II were carried out using the Very Large Telescope (VLT) SINFONI and Gemini-North/NIRI and presented in Trakhtenbrot et al. (2011, hereafter T11) which provided estimates of the SMBH masses ($M_{\text{BH}}$) and...
accretion rates of the quasars \( (L/L_{\text{Edd}}) \). These results indicated that the sample, on average, has higher accretion rates \( (L/L_{\text{Edd}} \sim 0.6) \) and lower masses \( (\sim 8.4 \times 10^8 M_\odot) \) than AGNs observed at lower redshifts.

Further observations were carried out with the Herschel Spectral and Photometric Imaging Receiver (SPIRE; Mor et al. 2012; Netzer et al. 2014, hereafter M12 and N14) and relied on data from the Spitzer Infrared Array Camera (IRAC; N14) 3.6 and 4.5 µm bands for positional priors for the Herschel photometry. While the majority of sources were detected using Spitzer, only nine source were detected in all three SPIRE bands. We define these Herschel/ SPIRE detections as “FIR-bright” sources, with an average FIR luminosity of \( L_{\text{FIR}} \sim 8.5 \times 10^{46} \text{erg s}^{-1} \ (2.2 \times 10^{13} L_\odot) \). By using the standard conversion factor based on the IMF of Chabrier (2003), we calculated star formation rates (SFRs) as SFR/\( M_\odot \) yr\(^{-1} = L_{\text{FIR}} / 10^{10} L_\odot \), giving SFRs \( \sim 1000-4000 M_\odot \) yr\(^{-1} \) for our nine FIR-bright sources. To determine the SFRs of the Herschel nondetected sources, which we refer to as “FIR-faint” sources, stacking analysis was carried out in N14 and gave a median SFR of \( \sim 400 M_\odot \) yr\(^{-1} \). The work of N14 and M12 indicate that there is a wide variation of SFRs in our sample, while we see in T11 that the variation of SMBH and AGN properties are more uniform across the sample.

The goal of the Herschel/SPIRE campaign was to determine the peak of the SF-heated dust continuum (M12 ; N14) and, if possible, observe evidence for merger activity. However, the size of the field of view and the spatial resolution of the data \( (\sim 18'' \), or \( \geq 100 \) kpc at \( z \simeq 4.8 \) ) were insufficient to determine the presence of close nearby systems.

### 2.2. ALMA Observations

Previously, in T17, we observed three FIR-bright and three FIR-faint quasars from our sample using ALMA. In this paper, we present an additional six FIR-bright and six FIR-faint quasars observed with ALMA. Thus, all of our original FIR-bright objects and 9/29 of our FIR-faint objects have been observed.

The 12 new targets were observed using ALMA Band 7 during the Cycle 4 period of 2016 November 9 to 2017 May 6. Our main goal is to detect and resolve the [C II] emission line, which is expected to have a width of several hundred km s\(^{-1} \) (T17), as well as a line-free dust emission continuum.

For consistency, we aimed to have the same spectral and spatial resolutions as T17. The observations were done with the C40-5 configuration, and the exposure time ranged from 1001 to 2276 s, with an observed angular resolution variation of 0''19-0''33 and a central frequency range of 317-349 GHz. The observed angular resolution corresponds to \( \sim 2 \) kpc at \( z \simeq 4.8 \). We chose the TDM correlator mode, which provides four spectral windows, each covering an effective bandwidth of 1875 MHz, which corresponds to \( \sim 1650 \) km s\(^{-1} \) at the observed frequencies. This spectral range is sampled by 128 channels with a frequency of 15.625 MHz, or \( \sim 15 \) km s\(^{-1} \) channel\(^{-1} \). The default spectral resolution of ALMA is given as roughly twice the size of the channels, i.e., \( \sim 30 \) km s\(^{-1} \). Two such spectral windows were centered on the frequency corresponding to the expected peak of the [C II] line, estimated from the Mg II-based redshifts of our targets (as determined in T11). Because of the specific redshifts of the sources, the spectral windows were found to be more affected by poor atmosphere transmission than those used during the observations of the six objects presented in T17, resulting in noisier [C II] data. The other two adjacent windows were placed at higher frequencies and separated from the first pair by about 12 GHz. Each of these pairs of spectral windows overlapped by roughly 50 MHz. However, the rejection of a few channels at the edge of the windows due to divergent flux values (a common flagging procedure in ALMA data reduction) leads to a small spectral gap between pairs of windows. This presents some issues for certain targets (Section 2.3). Given this spectral setup of four bands, the ALMA observations could, in principle, probe [C II] line emission over a spectral region corresponding to roughly \( \sim 3000 \) km s\(^{-1} \) (\( \Delta z \simeq 0.06 \)). Table 1 is an observation log with additional details of the ALMA observations. We will use abbreviated object names (i.e., “JHHMM”) in the rest of this paper.

### 2.3. Data Reduction

Data reduction was performed using the CASA package version 4.7.2 (McMullin et al. 2007). To create continuum and emission line images, CLEAN algorithms were run with Briggs weighting and a robustness parameter of 0.5. Continuum emission images were constructed using the line-free spectral window pair, while the UVCONTSUB command was used to subtract continuum emission from the [C II] window pair, resulting in continuum-subtracted cubes. Observed flux densities and beam-deconvolved continuum source sizes are presented in Table 2.

The sizes of the continuum emitting regions were determined from the respective images by fitting spatial 2D Gaussians to the sources, which are characterized by a peak flux, semimajor and semiminer axes, and a position angle. The fluxes were measured by integrating over these spatial 2D Gaussians. The sub-millimeter galaxy (SMG) companion to J2057 (see Section 2.4), however, seems to be composed of two separate sources that were not properly fitted by the CASA 2D Gaussian routine. Instead, sizes were obtained directly from the continuum images using an azimuthally averaged Gaussian fit. Since these values are not beam-corrected, they are quoted as upper limits in Table 2.

Various IMOMENTS commands gave the velocity fields and velocity dispersion maps (first and second moment, respectively) from the [C II] continuum-subtracted cubes. To measure the properties of the [C II] emission lines, we used both a “spatial” and a “spectral” method. In the spatial approach, we created zero-moment images (i.e., integrated over the spectral axis) for all sources and fitted the spatial distribution of line emission with 2D Gaussian profiles. Line fluxes were obtained as described before for the continuum flux determinations.

In the spectral approach, we extracted 1D spectra from the [C II] continuum-subtracted cubes. A Gaussian profile was fitted to the emission line profiles, from which we obtained the integrated line flux.

We found the two different methods described above to be in good agreement, with a median difference of 0.05 dex. As stated in T17, the spatial approach is less sensitive to the low signal-to-noise (S/N) outer regions of the sources and “wings” of the line profiles; thus, we adopt this method for our own analysis. However, J2057 has a spectral gap (as described in Section 2.2) lying in the center of the [C II] line. This proved difficult for the spatial method, as no interpolation of the missing line flux was possible. Hence, the line flux reported in Table 2 was obtained with the spectral approach. Also, both SMG companions to J1447 and J2057 (see next section) show...
separate dynamical components. In the case of J1447, the spectral approach was used to determine their properties. The J2057 SMG also breaks into two components in continuum emission that are not clearly related to the [C II] emission. Both components are characterized in Table 2.

2.4. Source Detections

Ten of our 12 new quasars are clearly detected in both continuum and [C II] emission with 6σ–12σ significance, while J1447 is only detected at a 3σ level in the [C II] line, and J1151 is not detected at all. Both J1447 and J1151 are FIR-faint sources. Because J1447 has a very weak signal, it was not possible to fit a Gaussian to the spatial distribution of its line and continuum emission. Instead, aperture photometry was carried out with an area corresponding to roughly the beam size. The [C II] emission of J1447 was found to have S/N ~ 3.6, while there was a non-significant signal in the continuum. The continuum values listed in Table 2 for J1447 and J1151 correspond to three times the average rms noise about the expected quasar positions.

Two FIR-faint quasars show the presence of companions detected in both continuum and [C II] emission with a significance of 6σ–9σ. Continuum maps for these two sources are presented in Figure 1. A continuum-only source is found separated from J2057 by 6'3 in the SE direction, which corresponds to 41.8 kpc at the redshift of the quasar and is marked with a "B" in Figure 1. We can put a lower limit of ~±1500 km s⁻¹ on the velocity shift of any [C II] emission from this source and the [C II] emission from the quasar host. Because of the separation and lack of a [C II] line detection, we conclude that this continuum source is most likely a source only seen in projection. A similar continuum-only source is found in T17, which is concluded to be a background/foreground projection. Information about companions can be found in Tables 1 and 2.

For all of our quasars detected in both continuum and [C II], the two emissions follow each other well. The exceptions are the two detected SMGs. Their detailed continuum and [C II] maps are presented in Figure 1. In the case of J1447, the continuum emission seems more extended toward the north than the [C II] emission, although weaker, redshifted [C II] emission appears toward the north in the dynamical maps (see next section). The SMG to J2057 has secondary peaks in [C II] and continuum emission. These are labeled as E, W and NE, SW in Figure 1, respectively. We will see in the next section that there is a strong indication of gravitational perturbations in these two SMG sources.

2.5. [C II] Line Properties

In Figure 2, we plot the continuum-subtracted [C II] spectral region for all 12 quasar hosts presented in this work, including J1151, which was undetected in both continuum and [C II], and J1447, which had a 3σ level detection in [C II]. We also include spectra for two SMGs accompanying J2057 and J1447. A best-fit line model using a Gaussian profile is overlaid. The rms spectrum is plotted below each emission line spectrum.

Figure 4 shows velocity maps for the 10 quasar hosts significantly detected in [C II] and the two SMGs accompanying J1447 and J2057. The weak [C II] emission from J1447 was not sufficient to determine moment maps. The morphologies of our targets are not as uniform as in T17, possibly due to some of our sources being observed through spectral submillimeter windows with worse transmission, as mentioned in Section 2.2. Well-behaved velocity maps with a clear velocity gradient across the system, which suggests rotation of a flat gaseous structure, are only seen in about half of systems. The remaining sources show noisier, more irregular maps, although evidence for a velocity gradient is still present.

As in T17, some of our quasar hosts show increased velocity dispersions in the centers of the [C II]–emitting regions, with σv ~ 100 km s⁻¹, which can be an indication of beam smearing. This could lead us to overestimate the rotation kinematics we see in Figure 4. However, we do not expand on correcting this smearing, as other studies of submillimeter sources have done, as our targets are only partially resolved and modeling the rotation is not possible. In fact, as many of our sources do not exhibit clear rotation-dominated kinematics (e.g., J1017 and J1654), other factors could be affecting the kinematics of our hosts. Possible alternatives, such as a turbulent component, have been demonstrated in several recent studies of resolved interstellar medium (ISM) kinematics in high-redshift galaxies (e.g., Gnerucci et al. 2011; Williams et al. 2014).

Notes.

a 3σ upper limit of the calculated rms at the expected position of the source.
b Line fluxes were determined by aperture photometry at the position of the source.
c Two Gaussian profiles were fitted to the [C II] line spectra. Source sizes have upper limits only.
d Two components are seen in continuum (NE and SW) and [C II] (E and W). Most source sizes have upper limits only.
The majority of our objects have a single peak line profile, except for J1404, which exhibits double peak emission in the $[\text{C} \text{II}]$ line, and the SMG companion to J1447. The double feature seen in J1404 has two peaks separated by $\sim 350$ km s$^{-1}$ from each other, while the SMG of J1447 shows two components to the $[\text{C} \text{II}]$ line separated by $\sim 600$ km s$^{-1}$.

The velocity map of J1404 in Figure 4 shows a single source with strong rotational signatures and a large total velocity amplitude of $\sim 400$ km s$^{-1}$, roughly the same separation we see in the spectrum. This FIR-bright source does not show the presence of companions, but the double peak could signal the late evolutionary stage of a merger event.

On the other hand, the double feature seen in the SMG of J1447 most likely corresponds to a double source. This is seen in the bottom right panel of Figure 4, where two spatially separated kinematic components appear. The NE peak is rather weak, as it is below the $3\sigma$ threshold of the $[\text{C} \text{II}]$ contours, but it is clearly recovered in the spectrum shown in Figure 2 and coincides with strong emission seen in the dust continuum (see Figure 1).

Finally, J2057 also presents some interesting dynamical features. Besides the presence of two dust continuum peaks and a complex velocity map shown by the companion SMG, the quasar itself shows strong evidence for dynamical disruption: its $[\text{C} \text{II}]$ emission appears as consistent with an $\sim 100$ km s$^{-1}$ rotating disk plus debris material and an $\sim 20$ kpc long collimated tadpole-like structure orientated roughly in the E–W direction, which is constrained to a very narrow velocity range. This structure is not apparent in Figure 4 because of the velocity binning. The object J2057 and its SMG companion will be the subject of a future paper.

Figure 1. Top: large-scale continuum images for the two FIR-faint quasars in our sample where companions have been found: J2057 and J1447. Note that J1447 is not detected in the dust continuum. The gray-scale maps show the continuum emission determined from the line-free ALMA spectral windows. Cyan and blue contours trace emission levels at different positive and negative significance levels, respectively, with the first contour tracing the region where the continuum emission exceeds $2\sigma$ and consecutive contours plotted in steps of $2\sigma$. The ALMA beams are shown as red ellipses at the bottom right of each panel. Physical companions, i.e., sources that have clear $[\text{C} \text{II}]$ detections with redshifts consistent with those of the quasars, are marked as “SMG.” The continuum source accompanying J2057 that lacks significant $[\text{C} \text{II}]$ emission is marked as “B.” Bottom: small-scale continuum and $[\text{C} \text{II}]$ line emission maps derived for the SMGs accompanying J1447 and J2057. For each source, the gray-scale map traces the continuum emission, while the contours trace the $[\text{C} \text{II}]$ line emission (i.e., surface brightness) at significance levels of $3\sigma$ and $6\sigma$. For each source, the line fluxes used for the contours were extracted from a spectral window spanning $\pm 500$ km s$^{-1}$ around the $[\text{C} \text{II}]$ line peak. The ALMA beams are shown as red ellipses at the bottom right of each panel. The two J2057 components observed in $[\text{C} \text{II}]$ emission are labeled E and W, while the two components seen in continuum are labeled NE and SW.
Figure 2. Spectra of the [C II] λ157.74 μm emission line for all of the new ALMA observations reported in this work. The FIR-bright sources are presented in the first and second row, FIR-faint sources in the third and fourth row, and accompanying SMGs in the bottom row. For each spectrum, the upper x-axis denotes the velocity offsets with respect to the redshift derived from the Mg II broad emission lines (T11). Red lines show the Gaussian fits to the line profiles. The rms spectra are also included in the same scale as the flux spectrum, except for J1151, where there is no [C II] detection.
2.6. Optical Center Separation

In Figure 3, we plot the continuum maps of our quasars along [C II] emission contours. From the second data release (DR2) of the Gaia mission (Gaia Collaboration et al. 2018a), cross-referenced with the Pan-STARRS I database (Flewelling et al. 2016), we obtain the optical centers of our objects.

We then compute the optical separation (OS) as the separation between the Gaia optical center and the peak of the dust continuum emission from our ALMA data, as determined by Gaussian fits in Section 2.3. Each image in Figure 3 lists the OS along with the associated error. The OS values have a range of $0.005 - 0.062$ for our entire sample. The median positional uncertainty of quasars in the DR2 of Gaia is $0.4$ mas (Gaia Collaboration et al. 2018b), while those objects that are cross-referenced with the Pan-STARRS database have median uncertainties of $3.1$ and $4.8$ mas for $\Delta$R.A. and $\Delta$decl., respectively (Chambers et al. 2016). The associated error of our OS considers uncertainties associated with the optical position, as well as our Gaussian fits to the continuum emission, giving an overall median error of $\sim 11$ mas.

Offsets of the optical center could be an indicator of dual-AGN or late-stage major mergers (Orosz & Frey 2013; Makarov et al. 2017). However, these studies found OS values on scales of hundreds of mas scales, much larger than what we see. We also see that there is no correlation between host galaxy velocity gradients and OS. In our sample, J1328–0224 is the object with the highest OS (62 mas), but Figure 4 shows that it has a very low gradient of velocity with rather uniform values. In contrast, J2057–0030 has the lowest OS, but we believe it to be a perturbed system with a tidal tail. Thus, we do not consider the OS to be an indicator of mergers or perturbations for our sources.

3. Results and Discussion

In what follows, we divide the discussion into those results that are robust and do not rely on unconstrained assumptions and those that are more speculative and need further observations in order to prove their veracity. In particular, the determination of gas and dynamical masses for our quasar hosts is highly uncertain; therefore, all discussion based on these determinations should be taken with extra caution.

3.1. Main Findings

3.1.1. Emission Line Velocity Offsets

Neutral carbon has a low ionization potential (11.3 eV) and can be excited by electron collisions. Therefore, [C II] emission can be found in the ISM throughout a galaxy, particularly tracing photodissociation regions, that is, naturally diffuse and partially ionized gas. Although it is seen from observations in the local universe that the [C II] line is broader than molecular gas (e.g., Goicoechea et al. 2015), because of its high brightness and narrow intrinsic width, it is a good measure of the systemic redshift of the quasar host galaxy. The Mg II line, produced in the vicinity of the SMBHs in the so-called broad-line region (BLR), is dominated by the gravitational SMBH, as well as other central bulk nuclear winds or turbulence. In Table 3, we compare the redshifts obtained from the [C II] and Mg II lines ($\Delta v_{\text{Mg} \, \text{II}}$) for our 17 quasar hosts with detected [C II]. For unobscured AGNs at moderate redshifts ($z < 2$), the BLR Mg II line is found within $\sim 200$ km s$^{-1}$ of the systemic redshifts (Richards et al. 2002; Mejía-Restrepo et al. 2016; Shen et al. 2016) and centered around $\sim 0$ km s$^{-1}$ (see Figure 2 in Shen et al. 2016). The large dispersions in the line shifts are clearly due to the broad nature of the BLR lines and hence the difficulties in determining precise line centers.

For comparison, we also list the SDSS-based redshift determinations published in Hewett & Wild (2010), along with the difference with respect to the [C II] line ($\Delta v_{\text{SDSS}}$). At $z \sim 5$, SDSS-based redshifts would be determined using the BLR UV $\text{Ly}_\alpha$, $\text{S IV}$, and $\text{C IV}$ emission lines, which are usually considered problematic because of the absorbed $\text{Ly}_\alpha$ profile, the weakness of the $\text{S IV}$ line, and the well-established blueshifts present in the $\text{C IV}$ line. In fact, we see no correlation between $\Delta v_{\text{SDSS}}$ and $\Delta v_{\text{Mg} \, \text{II}}$, most likely because of the uncertainties associated with the $z_{\text{SDSS}}$ determinations (Mason et al. 2017; Dix et al. 2020).

From Table 3, we can see that most objects in our total sample of 17 quasar hosts have significant blueshifts of the Mg II line with respect to the [C II] line ($\Delta v_{\text{Mg} \, \text{II}} > 0$). The average value for $\Delta v_{\text{Mg} \, \text{II}}$ is $464$ km s$^{-1}$, with a standard deviation of $657$ km s$^{-1}$, while the median is found to be at $379$ km s$^{-1}$. As Venemans et al. (2016) already pointed out, since the distribution of offsets is not centered around 0 km s$^{-1}$, we can assume that they are not due to the uncertainty associated with fitting the broad emission line of Mg II. This is further supported by Shen et al. (2016), who stated that the intrinsic uncertainty of using the Mg II broad line for estimating redshifts is $200$ km s$^{-1}$, smaller than our median offset. We find no noticeable correlation between Mg II offsets and the presence of companions.

Venemans et al. (2016) compiled a list of $z > 6$ quasars and compared the redshift measurements from the Mg II line and those of the CO molecular line or the [C II] atomic line. The median of the $z_{\text{C II}}/\text{CO} - z_{\text{Mg} \, \text{II}}$ distribution for their sample is $467$ km s$^{-1}$ with a standard deviation of $630$ km s$^{-1}$, almost identical to our findings. We created our own compilation but used exclusively quasars with a measured [C II] line for the sake of congruity. The compilation is populated by our total sample of 17 quasars, eight from Decarli et al. (2018), five from Willott et al. (2013, 2015, 2017), five from Venemans et al. (2012, 2016, 2017), two from Mazzucchelli et al. (2017), and one each from Banados et al. (2015) and Wang et al. (2016).

We present the Mg II offsets of this compilation as a histogram in Figure 5 and in Table 4. For this compilation, we found a mean $z_{\text{C II}} - z_{\text{Mg} \, \text{II}}$ of $372$ km s$^{-1}$, a median of $337$ km s$^{-1}$, and a standard deviation of $582$ km s$^{-1}$. It should be noted that only our sample is at $z \approx 5$, while the quasars from the literature are all at $z \approx 6$. The mean and median of the $z \geq 6$ only quasars are $300$ and $309$ km s$^{-1}$, respectively, very close to the results from our full compilation. This result strongly suggests a velocity difference between the BLR and quasar host galaxies of several hundred km s$^{-1}$.

Blueshifts are usually associated with outflowing gas that is approaching the observer. Blueshifts seen in the C IV line, for example, are usually interpreted as evidence for nuclear outflows, and they seem to correlate well with accretion rate (Coatman et al. 2016; Sulentic et al. 2017; Sun et al. 2018; Vietri et al. 2018; Ge et al. 2019). We have looked for such correlation for the objects in our compilation and found none. Figure 6 presents the accretion rate in units of Eddington (as reported in the literature) versus the measured [C II]–Mg II shifts. A rather low correlation coefficient is determined, with
Figure 3. Small-scale continuum and [C II] line emission maps derived from the Cycle 6 ALMA data for all sources with clear detection of [C II] line emission. The FIR-bright sources in our sample are in the top two rows, and the FIR-faint sources are in the bottom two rows. For each source, the gray-scale map traces the continuum emission, while the contours trace the [C II] line emission (i.e., surface brightness) at significance levels of 3σ, 6σ, 9σ, and 12σ. For each source, the line fluxes used for the contours were extracted from a spectral window spanning ±500 km s\(^{-1}\) around the [C II] line peak. The ALMA beams are shown as red ellipses at the bottom right of each panel. The optical position from Gaia is marked with a red plus sign. In the bottom left of each image, we list the OS along with the associated error.
Figure 4. The [C II] velocity maps for the FIR-bright sources in our sample (first and second rows), FIR-faint sources (third and fourth rows), and companion SMGs (bottom row). Black contours trace the [C II] emission line surface brightness at significance levels of 3σ, 6σ, 9σ, and 12σ. The ALMA beams are shown as hatched gray ellipses at the bottom right of each panel.
and Willott et al. \(\pm\) deviation of redshifted with respect to the MgII measurements with a mean and standard deviation of 372 \(\pm\) 582 km s\(^{-1}\). The vertical line denotes the median of 337 km s\(^{-1}\).

Figure 5. Histogram presenting the distribution of the velocity shifts of Mg II with respect to the [C II] emission lines of the quasars. Our 12 observations and those presented in T17 are at \(z \approx 4.8\), while those in Venemans et al. (2016) and Willott et al. (2013, 2015, 2017) are at \(z \gtrsim 6\). The [C II] line is clearly redshifted with respect to the Mg II measurements with a mean and standard deviation of 372 \(\pm\) 582 km s\(^{-1}\).

\(^b\) Sources with the presence of companions.

Figure 6. Eddington ratios of our compiled quasars against the observed Mg II offsets. References for the Mg II measurements and the Eddington ratios can be found in Table 4. The average Eddington ratio is 0.83. We plot a line in black to help illustrate that there are no objects with both high Mg II offsets and high Eddington ratios. In total, 36 quasars are plotted. Only five of the eight Decarli quasars have published Eddington ratios.

Table 4, giving a mean offset of \(\sim 0\) km s\(^{-1}\). Since the number of sources with companions is very small, these are by no means conclusive findings but suggest a possible link between merger activity and smaller [C II]–Mg II shifts.

3.1.2. SEDs and SFRs

We will rely on the rest-frame FIR continuum emission to estimate the total FIR emission of our objects. This will allow us to determine the SFRs of the host galaxies and nearby SMGs using the well-established relation between the FIR luminosity and the SFR (Kennicutt 1989). We include in this analysis the objects already presented in T17.

For our FIR-faint objects, this determination will be based only on the ALMA detection. For the FIR-bright objects, we will also use the Herschel measurements. We do not aim to perform a full modeling of the FIR spectral energy distribution (SED), as the number of photometric points available does not allow for a determination of the several physical parameters necessary for that, but rather determine which set of SEDs better represents the observations.

The contribution to the FIR SED from the AGN should be small, commonly given as \(\sim 10\%\) (e.g., Schweitzer et al. 2006; Mor & Netzer 2012; Rosario et al. 2012; Lutz et al. 2016). In this paper, we assume that the FIR emission of the sources in our sample is dominated by dust heated by SF activity (see full discussion and many references in Netzer et al. 2016 and Lani et al. 2017). The alternative view, which involves AGN-heated dust contributing significantly to the FIR SED, has been discussed in several publications (e.g., Leipski et al. 2014; Schneider et al. 2015; Siebenmorgen et al. 2015; Duras et al. 2017) but will not be addressed in this work. However, we do account for an additional error of the 250 \(\mu\)m Herschel/SPIRE.
band due to contribution from AGN-heated dust (as explained in N14, we add in quadrature an uncertainty estimated as 0.32 times the AGN luminosity at 1450 Å). Taking this effect into consideration increases the error of the 250 μm measurement by a factor of 1.67, on average. The ALMA absolute flux calibration in Band 7 is claimed to be of the order of 10%. We add this uncertainty in quadrature to the errors quoted in Table 2.

We use three different methods to produce model FIR SEDs for our sources. Because of the lower uncertainties in the ALMA measurements, this value usually dominates the fits for all three methods discussed.

For the first method, we use the grid of FIR SEDs provided by Chary & Elbaz (2001, hereafter CE01). These templates are unique in shape and scaling. The best-fit model is determined using the ALMA monochromatic luminosity and its associated uncertainty, while for the FIR-bright objects, we also include the Herschel measurements (values and errors from N14, with the 250 μm flux error corrected as explained above). For FIR-faint objects, the fit relies only on the ALMA measurement.

For the second method, we scale the SED determined by Magnelli et al. (2012), which corresponds to an average from the most luminous SMGs in their work. As before, the Herschel measurements are included for those quasars with detections at 250, 350, and 500 μm.

For the third method, we use a graybody SED. Following T17 and other works, we use a temperature of $T_d = 47$ K and dust emissivity coefficient $\beta = 1.6$. However, since some of our sources are not well fitted using this set of parameters, we also try graybody SEDs with a wider range of temperatures (40, 45, 50, 55, 60, and 70 K) and $\beta$ values (1.5 and 1.7). The determination of a best-fit temperature and $\beta$ is only possible for the FIR-bright, Herschel-detected sources. The mean $\chi^2$ for our nine FIR-bright quasars is $\sim 2$ (for 1 degree of freedom). We show the SED fits in Figure 7 together with the best-fit values, which are also reported in Table 5. We find that out of nine objects, seven are well fit by temperatures in the 40–50 K range.

Two require higher temperatures: J0331–0741 is best fit by a $\beta = 1.7$ and $T_d = 60$ K graybody SED, while J1616+0501

Figure 7. The FIR SEDs for the nine FIR-bright quasars in our sample, including those already presented in T17. Data points correspond to Herschel/SPire measurements at 250, 350, and 500 μm and ALMA detections at 895 μm (in the observed frame). For each source, four model SEDs are presented: dashed black lines represent the best-fitting FIR template from Chary & Elbaz (2001), while dotted red lines represent the scaled SED from Magnelli et al. (2012). A scaled graybody SED with $T_d = 47$ K and $\beta = 1.6$ is shown with solid yellow lines, while a best-fit model graybody SED is shown with solid green lines. The graybody best-fit parameters are included for each source.

needs $\beta = 1.7$ and $T_d = 70$ K. We briefly discuss these two cases next.

For J1616, all of the Herschel photometric points are found more than $3\sigma$ above the CE01 best-fit template, which is dominated by the scaling to the ALMA measurement. The corresponding SFR from the graybody best fit is $5275 M_\odot$ yr$^{-1}$, even higher than the $\sim 4200 M_\odot$ yr$^{-1}$ found by N14 based on Herschel data only. A similar, although not as extreme, case is J0331, whose data were already presented in T17. For J0331, N14 determined an SFR of $\sim 2100 M_\odot$ yr$^{-1}$, in good agreement with the value of 1922 $M_\odot$ yr$^{-1}$ we determine from the graybody best fit. Clearly, the high SFRs determined for these sources are driven by their very high Herschel luminosities. The high graybody temperatures, on the other hand, are the result of the correspondingly steep SEDs, which are found once the ALMA data are also taken into account.

Graybody temperatures as high as $T_d = 60–70$ are not expected for star-forming sources. However, temperatures as high as 70 or 80 K have been recently determined for a very small fraction of SMGs at high redshift (Miettinen et al. 2017), so these rather high ISM temperatures might not be totally unusual in the most luminous sources, although more observations are necessary in order to confirm this.

Once the total IR luminosity is determined by integrating the SED over the $8–1000$ $\mu$m range, the SFR is obtained using $SFR/M_\odot$ yr$^{-1} = L_{IR}/10^{10} L_{\odot}$, which assumes a Chabrier IMF. The results are presented in Table 5 as $L_{CE}$ and $SFR_{CE}$ for the CE01 fits, $L_{Mag}$ and $SFR_{Mag}$ for the Magnelli et al. (2012) fits, $L_{47K/31.6}$ and $SFR_{47K/31.6}$ for the graybody fit with fixed parameters $T_d = 47$ K and $\beta = 1.6$, and $L_{\text{bestGB}}$ and $SFR_{\text{best GB}}$ for the graybody fit with $T_d$ and $\beta$ left as free parameters.

For our total sample of 18 quasars, we see that the FIR-bright targets have an SFR range of $\sim 900–3200 M_\odot$ yr$^{-1}$, the FIR-faint objects have a range of $\sim 200–500 M_\odot$ yr$^{-1}$, and the SFRs of the SMGs cover $\sim 90–600 M_\odot$ yr$^{-1}$. The difference in the
| Subsample | Target | log $L_{\text{CE}}$ (L$_{\odot}$) | log $L_{\text{Mag}}$ (L$_{\odot}$) | log $L_{\text{47K/1.6}}$ (L$_{\odot}$) | $T_{\text{best GB}}$ (K) | $\beta_{\text{best GB}}$ | SFR$_{\text{CE}}$ ($M_{\odot}$ yr$^{-1}$) | SFR$_{\text{Mag}}$ ($M_{\odot}$ yr$^{-1}$) | SFR$_{\text{47K/1.6}}$ ($M_{\odot}$ yr$^{-1}$) | SFR$_{\text{best GB}}$ ($M_{\odot}$ yr$^{-1}$) |

Notes. $^a$ Sources from T17.

$^a$ Upper limit available for ALMA continuum flux.
determined SFRs using the different methods illustrates the systematic uncertainties of these calculations.

Besides the FIR-bright sources presented in Figure 7, Table 5 also lists the SFRs obtained for the FIR-faint sources. The SED best-fit values for J1447 are based on the ALMA continuum upper limit previously determined. We found this object to have an extremely low SFR of <20 M_☉ yr^(-1), maybe indicating that effective SF quenching has already occurred. The detection of [C II] in this host showcases how this line can be detected in the ISM of galaxies with very little ongoing SF. In the following sections, we will take the average SFR obtained from these methods as the representative SFR for each object. Errors will be computed as the maximum and minimum derived SFR.

3.1.3. The L_{AGN} versus L_{SF} Plane

Figure 8 presents the L_{AGN} versus L_{SF} plane. The FIR-bright and FIR-faint objects are shown with different colors, while the presence of companions is shown using different symbols.

Since our luminosity ranges in L_{AGN} and L_{SF} are rather narrow, it is not possible to draw conclusions about how our sources compare with those trends found by previous works for L_{AGN}- and L_{SF}-dominated sources. In fact, it has been a matter of great debate as to why the L_{AGN} versus L_{SF} plane shows significantly different trends depending on the way samples are defined (e.g., see discussion in Netzer et al. 2016). The answer to the apparent contradictory results seems to reside in the stochastic nature of AGN activity, with duty cycles much shorter than those that characterize SF (e.g., Hickox et al. 2014; Stanley et al. 2015; Volonteri et al. 2015). In short, selecting samples based on SFR and binning them in AGN power will give a representative L_{AGN}−L_{SF} relation, since the rapid (≈10^3−6 yr) changes in AGN power will be smoothed out, while selecting them in L_{AGN} and binning in L_{SF} will mix and match objects selected from their “unrepresentative” AGN luminosity and with very different SF power. These observed differences, however, seem to saturate at the highest luminosities.

In Figure 8, we include a 1:1 L_{AGN}−L_{SF} line as well as the trends determined by Netzer (2009; from observations at a wide redshift range) and Rosario et al. (2012; at z ≲ 2), both of which were defined for bright AGNs. However the Netzer (2009) trend is dominated by local samples, while the Rosario et al. (2012) samples are drawn from deep field surveys, hence neither consider the most powerful AGN. It is therefore not surprising that our optically flux-limited selected sample of quasars, on average, sits above both the Netzer (2009) and Rosario et al. (2012) relations. This is particularly true for the FIR-bright subsample. It would be of great interest to compare the L_{AGN} and L_{SF} distributions of our sources with those of higher redshift, like that of Decarli et al. (2018). However, quasars at z > 5 are very hard to find because of a strong contamination of late brown dwarfs, which introduces severe and complex selection biases to those systems (Banados et al. 2016).

Inspection of Figure 8 shows that the our FIR-bright and FIR-faint populations occupy distinctively different regions of the diagram, even though the individual distributions of these two properties do not show evidence for two separated populations, as can be seen in the bottom panel of Figure 8. This can also be seen in Figure 2 of N14 as λ_{A}(3000 Å), who analyzed the Herschel observations of z ~ 4.8 quasars, including all of our FIR-bright and FIR-faint sources, and 20 further FIR-faint sources. From this work, it becomes clear that FIR-bright and FIR-faint sources dominate at the high and low end of the black hole (BH) mass distribution, respectively, but with no indication of a bimodality. In fact, the distributions of the source properties indicate a clear relation between BH mass, L_{AGN}, and SFRs with the median M_{BH}, L_{AGN}, and L_{SF} of the FIR-bright sources (9.28 M_☉, 10^{47.13} erg s^(-1), and 10^{46.91} erg s^(-1), respectively) being higher than those of the FIR-faint sources (8.85 M_☉, 10^{46.78} erg s^(-1), and 10^{46.23} erg s^(-1)). For a more in-depth discussion, see N14.

We find a weak correlation coefficient between L_{AGN} and L_{SF} for our entire sample (r = 0.55); however, more extensive studies (e.g., Stanley et al. 2015, 2017; Lanzuisi et al. 2017) indicate that much larger samples are required to draw conclusions. We will return to the issue of the possible segregation observed in the L_{AGN} versus L_{SF} plane in Section 3.1.6.
We derive dust masses for our full sample of 16 continuum-detected quasars and find a range of $M_{\text{dust}} \sim 2-15 \times 10^9 M_\odot$ (see Table 5). Upper limits of $\sim 10^8$ and $\sim 10^9 M_\odot$ are found for the J1151 and J1447 hosts, respectively. The average value is larger for FIR-bright objects than for FIR-faint objects, with dust masses of $10^{8.7}$ and $10^{8.4} M_\odot$, respectively. In Table 5, we also determine dust masses for the FIR-bright objects using the best-fit values of $T_{\text{bestGB}}$ and $\beta_{\text{bestGB}}$ discussed in Section 3.1.2. However, we note that due to the small range of $T$ and $\beta$ and the dominance of the continuum flux density and luminosity distance, the differences in these calculations from assuming $T_d = 47$ K and $\beta = 1.6$ are minor.

3.1.5. Companion Detections

Current cosmological models recognize high-$z$ quasars as signposts of high-density environments (see Costa et al. 2014 and references therein). It is therefore not unexpected that our sample shows a larger number of companions when compared to ALMA observations of blank fields.

Recent blank deep field surveys conducted with ALMA (Carniani et al. 2015; Aravena et al. 2016a; Fujimoto et al. 2016) imply that each ALMA pointing of $18''$ should have of the order of $\sim 0.1$ SMGs at a flux limit of 15 mJy at 1.2 mm. Other measurements of the Hubble Space Telescope (HST) Legacy Fields (Bouwens et al. 2015) and the Great

Notes. T17 Sources from T17.

a Calculated using the inclination angle corrections derived from the sizes of the [C II] emitting regions.

b Calculated assuming the CE01-based SFRs.

c Best-fit values are $T_{\text{bestGB}}$ and $\beta_{\text{bestGB}}$ from Table 5.

d BH masses taken from T11.

e Calculated assuming $M_{\text{BH}} = (1 - \eta) L_\text{bol} / \eta c^2$, with $\eta = 0.1$.

f Dynamical masses based on an estimate of the size of the J1447 host.

g No dust continuum detections.

3.1.4. Dust Masses

The continuum emission at rest wavelength $\sim 152$ $\mu$m can also be used to calculate dust masses for our objects assuming that the FIR continuum flux originates from optically thin dust at these wavelengths. Using the same methods as in Dunne et al. (2000) and Beelen et al. (2006; see also Scoville et al. 2016), the dust mass can be calculated as

$$M_d = \frac{S_{\text{rest}} D_L^2}{\kappa_d(\lambda_{\text{rest}}) B(\lambda_{\text{rest}}, T_d)}, \quad (1)$$

where $\kappa_d(\lambda) \propto \lambda^{-\beta}$ is the wavelength-dependent dust mass opacity, $S_{\text{rest}}$ is the continuum flux density at $\lambda_{\text{rest}}$, $B(\lambda_{\text{rest}}, T_d)$ is the monochromatic value of the Planck function at $\lambda_{\text{rest}}$ for temperature $T_d$, and $D_L$ is the luminosity distance. Here $\kappa_d$ is found to be 0.077 $m^2$ $k$ $^{-1}$ at 850 $\mu$m (Dunne et al. 2000); hence, $\kappa_d(\lambda_{\text{rest}}) = 0.077 (850/\lambda_{\text{rest}})^{1.3} m^2$ $k$ $^{-1}$. To calculate the dust mass, we assume $T_d = 47$ K and $\beta = 1.6$.

We note from Equation (1) that the only formal error comes from the measurement of the continuum flux, while systematic errors will arise from our assumption of the adopted SED and the opacity coefficient, which will dominate. However, as we are using very similar parameters to those adopted in the literature, a direct comparison of results is possible.
Observatories Origins Deep Survey (GOODS) Fields (Stark et al. 2009) give surface densities on the order of 0.01 galaxies per single ALMA Band 7 pointing (for SMGs with SFR $\sim 100 M_{\odot}$ yr$^{-1}$). Though they have not been confirmed with higher S/N, Aravena et al. (2016b) cited a number count of roughly 0.06 [C II]--emitting $z \sim 5$--8 galaxies per ALMA pointing of the Hubble Ultra Deep Field.

As quasars, SMGs are also highly clustered and seem to be hosted by massive dark matter halos (Wilkinson et al. 2017). Besides, several works have found a substantial fraction of submillimeter sources with multiple components varying from 35% to 80%, depending on resolution and flux limit (Hodge et al. 2013; Bussmann et al. 2015; Scudder et al. 2016; Hayward et al. 2018).

In a recent study of the multiplicity of FIR-bright quasars, Hatziminaoglou et al. (2018) assembled a random sample of 28 IR-bright SDSS quasars with detections in Herschel/SPIRE. This sample of detected quasars would correspond to our FIR-bright objects in terms of $L_{\text{AGN}}$, $M_{\text{BH}}$, and Eddington ratios but with $z \sim 2$--4. Using the ALMA Atacama Compact Array (ACA), Hatziminaoglou et al. (2018) found that 30% of their targets were multiple. However, their observations do not provide the same depth or resolution as our own, and the redshifts of their submillimeter sources were not confirmed.

Decarli et al. (2017, 2018) presented a similar study of [C II] and dust continuum at a similar redshift to our study, where the ALMA observations provide enough information to indicate whether the nearby sources are real companions. They found that 4/25 rapidly star-forming galaxies have a companion, i.e., 16%. Based on the IR luminosities reported by Decarli et al. (2018), 20 quasar hosts would be classified as FIR-faint for a threshold FIR luminosity of $10^{12.9} L_{\odot}$, and 3/4 of the companions would be associated with FIR-faint quasar hosts.

With the two newly observed companions we present here, our total observed sample of 18 quasars has five sources with companions, one FIR-bright (J1511) and four FIR-faint (J0923, J1328, J2057, and J1447), i.e., 28%. The objects J0923 and J1328 have no nearby sources in Spitzer/IRAC, while J2057 and J1447 were not observed by Spitzer, and J1511 (T17) has two further nearby Spitzer/IRAC sources. It is interesting that we only find that one FIR-bright target is multiple in ALMA observations, a rate much lower than that found in the randomly selected FIR-bright sample of Hatziminaoglou et al. (2018), and that we find a percentage of companions slightly higher than that reported by Decarli et al. (2017).

3.1.6. Major Mergers among Hosts

Different lines of evidence suggest that mergers among gas-rich galaxies should drive the most luminous AGN and most powerful SF of their hosts. This is proposed by numerical simulations (Hopkins et al. 2005, 2008) and backed by observations at low- and high-$z$ (Treister et al. 2012; Glikman et al. 2015; Koss et al. 2018). Thus, our initial expectations were to find that our ALMA observations would show that the FIR-bright sources are powered by major mergers of gas-rich galaxies and that the FIR-faint sources, found closer to the main sequence (MS) of galaxies, could be evolving through a secular process or also involved in mergers. The evidence would emerge from the presence of close companions to our quasars.

We find that of the $\sim 28\%$ of host galaxies with companions, the majority are FIR-faint sources (one FIR-bright and four FIR-faint). One FIR-bright source, J1404, presents an unusual [C II] double peak that could signal a late-stage merger. Bischetli et al. (2018) found three companions around their targeted $z = 4.4$ quasar, two of which have double-peaked line emission, while in Willott et al. (2017), the high spectral and spatial resolution allows them to attribute different peaks in the [C II] line to the quasar source, a 5 kpc separated companion, and a “central excess” component between the two.

The preference for companions in FIR-bright quasars could then be explained if these correspond to very early stages in the merger process, while the FIR-bright systems correspond to much later stages, when the progenitor galaxies are no longer resolved by our ALMA observations. The lack of disturbances in the velocity fields of our systems does not oppose this argument, as observations of the ISM in low-$z$ mergers demonstrate that the central core of mergers rapidly settles into a rotating-dominated system (Ueda et al. 2014).

The lack of clear, ongoing mergers among our systems could be explained as a sample bias, since our quasars were optimally selected. Glikman et al. (2015) showed that for a sample of 2MASS-selected dust-reddened quasars at $z \sim 2$, 8/10 hosts show clear evidence for very close, interacting companions. Similar results were found by Urrutia et al. (2008) for dust-reddened quasars at $z \sim 0.4$--1.0. The nuclei are so heavily dust-enshrouded that HST follow-up clearly revealed the perturbed hosts. These type of quasars would not be found in our parent sample. It is then possible that the distinct populations observed in the $L_{\text{AGN}}$--$L_{\text{SF}}$ plane (Figure 8) reflect the properties of the very early and very late mergers just mentioned.

3.2. Other Determinations

3.2.1. Dynamical Masses

The [C II] line can be used to estimate the dynamical masses ($M_{\text{dyn}}$) of the quasar host galaxies and the companion SMGs. We use the same method as in T17 and several other studies of [C II] and CO emission in high-redshift sources, which assumes the [C II]--traced ISM is arranged in an inclined, rotating disk (Wang et al. 2013; Willott et al. 2015; Venemans et al. 2016), and determine $M_{\text{dyn}}$ as

$$M_{\text{dyn}} = 9.8 \times 10^8 \left( \frac{D_{\text{[C II]}}}{\text{kpc}} \right) \left( \frac{\text{FWHM}_{\text{[C II]}}}{100 \text{ km s}^{-1}} \right)^2 \frac{1}{\sin^2 (i)} M_{\odot}. \tag{2}$$

In this relation, $D_{\text{[C II]}}$ is the size of the [C II]--emitting region measured by the deconvolved major axis of the Gaussian fit of said region (see Table 2). The $\sin (i)$ term reflects the inclination angle between the line of sight and the polar axis of the host gas disks, with the circular velocity given as $v_{\text{circ}} = 0.75 \times \text{FWHM} / \sin (i)$. Here $i$ is determined from the ratio $\cos (i) = (a_{\text{min}} / a_{\text{maj}})$, where $a_{\text{min}}$ and $a_{\text{maj}}$ are the semiminor and semimajor axes of the [C II]--emitting regions, respectively. These masses can be found in Table 6, where we list $M_{\text{dyn}}$, as well as its inclination-uncorrected value (i.e.,
We find that the FIR-bright and FIR-faint systems have comparable $M_{\text{dyn}}$ values. The mean is $9 \times 10^{10} M_\odot$. We also note that among the interacting SMGs reported in this work, the companion to J1447 is of particular interest. Its two [C II] spectral components taken individually, each with unresolved sizes, would correspond to systems with comparable dynamical masses found at the lower end of the observed range presented in Table 6. Therefore, they would represent a major merger between these two components but a likely minor merger with the quasar host. Note, however, that the dynamical mass of the J1447 host is also particularly uncertain, due to the weakness of the [C II] detection.

This method of deriving the dynamical mass carries significant uncertainties, due to the several assumptions required to derive them and the limited spatial resolution data available for our systems. A large contributor to the error is our measurement of the major and minor axes of the [C II]–emitting region, from which we derive $i$ and $D_c$. We estimate a mean error of 0.44 dex by propagating systematic uncertainties and the uncertainties of our measured values.

However, the most significant assumption is that we are observing inclined rotating disks. Only 4/6 of our FIR-bright and possibly 2/4 of our FIR-faint objects show clear indications of a smooth and coherent velocity gradient, as can be seen in Figure 4. Furthermore, note that even a smooth and coherent velocity gradient does not guarantee a rotation-dominated host galaxy. We can compute the dynamical masses assuming the case of pure dispersion-dominated gas (Decarli et al. 2018),

$$\begin{align*}
M_{\text{Disp}} &= \frac{3}{2} \frac{a_{\text{maj}} \sigma_{\text{line}}^2}{G},
\end{align*}$$

where $\sigma_{\text{line}}$ is the line width of the Gaussian fit of the [C II] spectrum, $G$ is the gravitational constant, and $a_{\text{maj}}$ is the major axis of the [C II] region. We find that the dynamical masses we derive from assuming dispersion-dominated gas are lower than both the inclination-corrected and noncorrected dynamical masses derived from assuming a rotating disk, with a mean of $2.4 \times 10^{10} M_\odot$ for $M_{\text{Disp}}$ (see Table 5). Dynamical masses derived from assuming dispersion-dominated gas can be regarded as a lower limit to the true dynamical mass. We will use the dynamical masses obtained assuming an inclined, rotating disk throughout the rest of this work in order to be comparable to similar studies in the literature.

### 3.2.2. Gas Masses

We can determine gas masses, $M_{\text{gas}}$, making use of a gas-to-dust ratio (GDR) of 100, as determined at low-z (Draine et al. 2007). Recent studies comparing gas mass estimates obtained from CO line measurements and dust masses obtained from FIR emission have given a wide range of GDRs for high-redshift systems ($\sim$30–100; Ivison et al. 2010; Aravena et al. 2016c; Banerji et al. 2017). This is an unexpected result, since it is well established that high-z galaxies are characterized by lower metallicities at all galaxy masses (Lian et al. 2018) and that the GDR is inversely proportional with metallicity (Rémy-Ruyer et al. 2014; De Vis et al. 2019). However, as discussed in Aravena et al. (2016c) and Banerji et al. (2017), another interpretation for these results is to assume a “normal” GDR and revisit the determination of the CO luminosity to total gas conversion factor. Both the GDR and CO luminosity to total gas fraction are highly dependent on galaxy properties, such as surface density, compactness, and particularly metallicity. In summary, and for a more straightforward comparison with other works, we adopt a GDR of 100.

Gas masses are derived from dust masses in Table 6 and are found to be large, in the $10^{10}$–$10^{11} M_\odot$ range. For four of our FIR-bright systems, $M_{\text{gas}}$ is larger than the dynamical masses by factors of up to 3, while for only one FIR-faint system, $M_{\text{gas}} \sim 0.9 \times M_{\text{dyn}}$, the remaining systems have factors ranging from 0.7 to 0.2.

In general, the estimated ISM masses for our quasars are comparable to their dynamical masses. For our FIR-bright sources, 6/9 show $M_{\text{gas}} \geq M_{\text{dyn}}$ by factors of 1–3 (the unphysical finding that $M_{\text{gas}} > M_{\text{dyn}}$ would be alleviated had we adopted a GDR as low as 30, as discussed above). This is not seen for the FIR-faint sources, suggesting that FIR-bright objects are more gas-rich than FIR-faint systems. Defining $f_{\text{gas}} = M_{\text{gas}}/M_{\text{dyn}}$, we find for those objects where $M_{\text{gas}} < M_{\text{dyn}}$ that $f_{\text{gas}} = 0.2$–1.0.

#### 3.2.3. The MS at $z \sim 5$

We want to compare our full quasar sample with galaxies found on the stellar mass–SFR sequence for star-forming systems, the MS, at similar redshifts. However, we only have estimates for the total dynamical and gas masses of our quasar hosts, not of their stellar masses. In principle, these could be obtained by calculating $M_* = M_{\text{dyn}} - M_{\text{gas}}$. From the measured values, there is a strong indication that most of the quasar hosts are very gas-rich, with $M_{\text{gas}} = 0.3$–4.0 $M_*$, for those objects where $M_{\text{gas}} < M_{\text{dyn}}$ and possibly higher for those objects where $M_{\text{gas}} > M_{\text{dyn}}$. As already explained, the uncertainties on these values are significant.

An alternative approach is to adopt a gas fraction measured in nonactive high-z galaxies where the stellar mass can be determined directly, which is not possible for our sample because of the dominance of the AGN continuum at rest-frame NIR and optical bands. These determinations have been done out to $z \sim 4$ (Schinnerer et al. 2016; Dessauges-Zavadsky et al. 2017; Darvish et al. 2018; Gowarhan et al. 2019) and found $f_{\text{gas}} \sim 0.5$–0.8 (considering no dark matter), where a strong dependence with redshift and no correlation with environment are also seen (Darvish et al. 2018). We can then conservatively assume that for our systems, $f_{\text{gas}} = M_{\text{gas}}/M_{\text{dyn}} = 0.6$, and therefore $M_* = 0.4 M_{\text{dyn}}$.

In Figure 9, we plot two MS curves. One is the parameterization given in Equation (9) of Schreiber et al. (2015) for the redshift range $4 < z < 5$ after correcting for the different adopted IMF (Schreiber et al. 2015 used a conversion factor of SFR to $L_{\text{SFR}}$ 1.7 times larger than our own). The second curve is from Tomczak et al. (2016) for galaxies at redshifts $0.5 < z < 4$. Both MS curves agree well with each other.

We find that the majority of our sources lie above the MS curves. If we used dynamical mass values derived from assuming dispersion-dominated gas, our objects would shift to the lower stellar mass regime and sit even higher above the MS, as seen in Figure 9. Clearly, all of our FIR-bright quasars are found in the starbursting domain and at least 1 dex from the MS. Their SFRs are only comparable to the brightest known...
SMGs. Some of the FIR-faint sources sit within 1σ of the MS of star-forming galaxies at those early epochs, but again, the majority of our faint sources sit above the MS. Note that our division into FIR-bright and FIR-faint sources is completely arbitrary, and the determined SFRs for our full sample are indeed a continuous distribution, as shown in the bottom panel of Figure 8.

3.2.4. SMBH–Host Galaxy Mass Relation

In Figure 10, we plot the stellar masses of our quasar hosts against their BH masses for the full sample of nine FIR-bright and eight FIR-faint quasars detected in [C II]. As before, we have adopted $M_\star = 0.4 M_{\text{dyn}}$. However, it is likely that the real values of $M_\star$ would broaden the observed distribution, which now corresponds to a net shift of the observed $M_{\text{dyn}}$ distribution. The BH masses were taken from T11 and are based on Mg II measurements. We find that the average BH mass of our sample is $10^{9.2} M_\odot$, with a slight difference between the BH properties of FIR-bright and FIR-faint objects. The FIR-bright objects have an average $M_{\text{BH}}$ of $10^{9.4} M_\odot$ and Eddington ratio of $L/L_{\text{Edd}} \sim 0.65$, while FIR-faint objects have an average $M_{\text{BH}}$ and Eddington ratio of $10^{8.9} M_\odot$ and 0.78, respectively. We find a mean $M_{\text{BH}}/M_\star$ ratio of 1/19, with FIR-bright sources having $M_{\text{BH}}/M_\star = 1/15$ and FIR-faint systems $1/28$.

We compare our sample with the local massive elliptical galaxies (Kormendy & Ho 2013). Figure 10 shows the positions of local galaxies with an $M_{\text{BH}}/M_\star$ ratio ranging from $\sim 1/100$ to $\sim 1/1000$, the ratios being strongly correlated with mass. While the BH masses of our sample of high-$z$ luminous quasars are found at similar values as seen in the local universe, the stellar masses are, on average, 1 order of magnitude lower. This is similar to the results found by other groups and in good agreement with the direct detection of two quasar hosts at $z \sim 4$ (Targott et al. 2012). A higher-redshift sample of three quasars at redshift $z \sim 6.8$ with available $M_{\text{BH}}$, $M_\star$, $L/L_{\text{Edd}}$, and SFR is found in Venemans et al. (2016). The $M_{\text{BH}}$ values were taken from De Rosa et al. (2014). When compared to our own sample in Figure 10, we see that they sit between the FIR-bright and FIR-faint objects with an average $M_{\text{BH}}/M_\star$ ratio of 1/19, the same as our sample. In terms of their AGN properties, they are found at the top end of the mass distribution of $z \sim 6$ sources presented in T11 but at the low end in terms of $L/L_{\text{Edd}}$. Their SFRs are somewhat in between our BH and stellar components, assuming constant mass growth rates over a period of 50 Myr. Filled stars with black arrows indicate average values and growth for both FIR-bright and FIR-faint objects. Our plotted sources have a typical error of 0.44 dex for $M_\star$ (from our own estimates) and 0.4 dex for $M_{\text{BH}}$ (derived in T11).

Assuming that the stellar mass of the quasar host galaxies grows only due to the formation of new stars (i.e., neglecting possible mergers), we can use our SFR estimates from Section 3.1.2 to calculate the growth rate of $M_\star$, i.e., $\dot{M}_\star$. The instantaneous growth rate of the BHs can be computed as the mass accreted onto the BH that does not convert into energy, $M_{\text{BH}} = \dot{M}_{\text{bol}}$, where $\dot{M}_{\text{bol}}$ is the bolometric luminosity from T11 using the rest-frame UV continuum emission. We assume the radiative efficiency to be $\eta = 0.1$.

As in T17, we find that all systems have $M_{\text{BH}}/M_\star > 1/200$, and typical values are found to be $\sim 1/54$ (see Table 5), with the FIR-bright and FIR-faint systems having medians of $M_{\text{BH}}/M_\star \sim 1/71$ and 1/27, respectively.

Assuming that the calculated instantaneous growth rates continue for a period of time, we can determine the migration
that our sources would undergo on the $M_{\text{BH}}$ versus $M_*$ plot. The time span needs to be determined under reasonable assumptions. Typical SF timescales derived at lower redshifts might not be applicable to our sample. Using the determined $M_*$ and SFRs, we can find the depletion time for the observed reservoir of gas. This is found to be between 20 and 100 Myr. Hence, we will adopt a general time span of 50 Myr, which is also what was used in T17.

As already discussed, because of the stochastic nature of AGN activity, with duty cycles shorter than those of SF by 1 or perhaps up to 2 orders of magnitude (e.g., Hickox et al. 2014; Stanley et al. 2015; Volonteri et al. 2015), the instantaneous $M_{\text{BH}}$ values measured for single objects might not be the best proxy to characterize BH growth over the time required for the buildup of a sizable stellar mass due to SF. Instead, the value averaged over our entire sample will result in better determination of the “typical” $M_{\text{BH}}$. The resulting “growth tracks” are shown in Figure 10. We also obtained the means of $M_{\text{BH}}$ and $M_*$ separately for the FIR-bright and FIR-faint subsamples and have plotted them in Figure 10. For most objects, these tracks suggest a larger future growth of stellar mass over BH mass, which is necessary to bring them closer to the local population of elliptical galaxies.

4. Summary and Conclusion

We have presented new Band 7 ALMA observations for 12 new luminous quasars at $z \approx 4.8$ to reach a total sample size of 18 sources, which are divided into Herschel/SPIRE-detected (FIR-bright) and Herschel/SPIRE-undetected (FIR-faint) systems. The data probe the rest-frame FIR continuum emission that arises from dust heated by SF in the host galaxies of the quasars and the $\text{[C II]} \lambda 157.74 \mu \text{m}$ emission line from the host ISM. The ALMA observations resolve the continuum- and line-emitting regions on scales of $\sim 2$ kpc.

Our main findings for our total sample of 18 targets is as follows.

1. Five out of 18 of our quasars have companions; four of the quasars are FIR-faint, and one is FIR-bright. The companions are separated by 15–60 kpc. The quasar hosts with companions have an SFR rate of $\sim 220$–$3200 \ M_\odot \text{ yr}^{-1}$. The companions are forming $90$–$580 \ M_\odot \text{ yr}^{-1}$, which is generally lower than the SFR measured for the quasar hosts.
2. The dynamical masses of the quasar hosts, estimated from the $\text{[C II]}$ lines, are within a factor of $\sim 3$ of the masses of the interacting companions, supporting an interpretation of these interactions as major mergers.
3. For all of our sources, we find that the gas mass is comparable to the dynamical mass, suggesting that some of them could be kinematically dominated by the ISM component.
4. The $\text{[C II]}$–based dynamical masses show that our systems are above the MS of star-forming galaxies. When comparing $L_{\text{AGN}}$ versus $L_{\text{SF}}$, we find evidence that the FIR-bright and FIR-faint subsamples are separated. We tentatively interpret this result as an evolutionary sequence within merger evolution, but great caution must be exercised, as this is based on small number statistics.
5. Compared with the BH masses, the $\text{[C II]}$–based dynamical host masses are generally lower than what is expected from the locally observed BH-to-host mass ratio.

6. We have found a clear blueshift of Mg II with respect to our $\text{[C II]}$ measurements that is not observed at lower redshifts. No correlation is found between the shift and the presence of companions or the accretion rate of the SMBHs.
7. The lack of companions to most of our quasar hosts may suggest that processes other than or besides major mergers are driving the significant SF activity and fast SMBH growth in these systems. Alternatively, the systems could be observed at very different stages of the merger process, with most FIR-faint sources found at the early stages, while FIR-bright sources are found at very late phases.

This paper makes use of the following ALMA data: ADS/ JAO.ALMA##/2016.1.01515.S. ALMA is a partnership of the ESO (representing its member states), NSF (USA), and NINS (Japan), together with the NRC (Canada), NSC and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by the ESO, AUI/NRAO, and NAOJ. N.N. and P.L. acknowledge funding from Fondecyt project No. 1161184. R. M. acknowledges support from the ERC advanced grant 695671 QUENCH and support by the Science and Technology Facilities Council (STFC).
