DOI: https://doi.org/10.3201/eid2707.203348

Paenibacillus thiaminolyticus is a nonvirulent organism found in human and ruminant microbiota. However, P. thiaminolyticus can act as an opportunistic pathogen in humans. We describe a case of abdominal wall hematoma secondarily infected by P. thiaminolyticus. Our findings emphasize the risk for unusual Paenibacillus infections in otherwise healthy persons.

The genus Paenibacillus comprises a growing number of species of rod-shaped, motile bacteria with peritrichous flagella (1). Paenibacillus species share 89.6% similarity of 16S rDNA gene sequences and grow as nonpigmented colonies on tryptic soy agar (1). Best known as a nearly ubiquitous environmental bacteria, many Paenibacillus species are potential opportunistic pathogens in humans (2). We report a case of isolated surgical site infection caused by P. thiaminolyticus in an otherwise healthy patient.

A 33-year-old woman came to the emergency department with a fever and reported having a painful and fluctuating abdominal wall mass for 3 days. She had undergone lipoabdominoplasty in a different hospital 7 days earlier. Laboratory tests showed anemia (hemoglobin 88 g/L, hematocrit 0.24 L/L) and isolated C-reactive protein elevation (117 mg/L). Computed tomography of the abdomen demonstrated a fluid collection in the abdominal wall measuring 22 × 9.5 × 5 cm. The patient was admitted for observation. Blood cultures performed at 38.5°C showed no bacterial growth.

Empirical intravenous antimicrobial drug therapy for suspected infected hematoma was initiated with amoxicillin/clavulanate (2.2 g 3×/d), according to local hospital guidelines. Under antimicrobial drug treatment, the patient’s fever resolved, but her abdominal pain persisted.

On day 3, we aspirated a sample of the fluid collection in the abdominal wall for microbiological examination. The aspirate was cultured on blood agar incubated at 35°C with 5% CO₂ for 48 h; on MacConkey
agar incubated at 35°C, aerobic, for 24 h; and on selective anaerobic agar at 35°C, anaerobic, for 5 days. All 3 yielded a pure culture of gram variable rod-shaped bacteria. We used Biotype matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (Bruker Corporation, https://www.bruker.com) and the Bruker mass spectra database, which returned *Paenibacillus thiaminolyticus* with a best-match score of 2.07 (a score ≥2 means identification at the species level) (3,4).

On day 7, the patient had bleeding at the surgical site, and we performed a surgical evacuation with drainage of the fluid collection. We took an intraoperative microbiological swab specimen and ran another MALDI-TOF mass spectrometry analysis, which confirmed the pathogen as *P. thiaminolyticus* with a best match score of 2.17.

After evacuation of the hematoma, the patient rapidly recovered. Because no specific clinical breakpoints have been established for *Paenibacillus* spp., we used nonspecies related clinical breakpoints from the European Committee on Antimicrobial Susceptibility Testing pharmacokinetics and pharmacodynamics (Table).

| Antimicrobial drug | MIC (mg/L) | SSC (mg/L) |
|--------------------|------------|------------|
| Amoxicillin/clavulanate | 0.064 | 1.2 |
| Tetracycline | 12 | 2.8 |
| Trimethoprim/sulfamethoxazole | <0.094 | 1.5–3 |
| Clindamycin | 0.38 | 23 |
| Ciprofloxacin | 0.19 | 4.56 |

Table. Comparison of MIC and SS of antimicrobial drugs in blood 4 hours after intravenous administration to treat *Paenibacillus thiaminolyticus* in a patient, Switzerland*

*No specific clinical breakpoints have been established for *Paenibacillus* spp. We used European Committee on Antimicrobial Susceptibility Testing pharmacokinetics and pharmacodynamics to determine antimicrobial susceptibility. SSC, steady state concentration.

†Antimicrobial drugs were administered at the recommended doses reported in the manufacturer the data sheets (compendium.ch; https://compendium.ch).

‡Trimethoprim/sulfamethoxazole is dose dependent.

In summary, this case is a reminder of the existence of a rare potential pathogen in our microbiota, although the causality might be discussed because *Paenibacillus* spp. remain mostly environmental bacteria. Therefore, identification relies on MALDI-TOF mass spectrometry or 16S rRNA gene sequencing. Surgical debridement of the infection focus also is recommended. The microorganism shows a variable antimicrobial susceptibility profile, and trimethoprim/sulfamethoxazole and amoxicillin/clavulanate are possible first choice empiric therapies after successful identification.

Acknowledgments

We thank the patient for permission to share and publish her case. We also thank the clinical microbiology team of Kantonsspital Luzern for their assistance with biotyping.
Confirmed Cases of Ophidiomycosis in Museum Specimens from as Early as 1945, United States

Ophidiomycosis represents a conservation threat to wild snake populations. The disease was reported in North America early in the 21st century, but the history of ophidiomycosis has not been investigated. We examined museum specimens and confirmed cases of ophidiomycosis >50 years before the disease’s reported emergence.

Emerging fungal pathogens of wildlife are recognized as major threats to global biodiversity, causing population declines and extinction events in a variety of host species (1). Ophidiomyces ophidiicola, the causative agent of ophidiomycosis, is one such pathogen recognized as a conservation threat to wild snakes (2). The disease first gained attention in 2008 when fatal infections emerged in eastern massasauga rattlesnakes (Sistrurus catenatus) in Illinois, USA (3), and has since been documented throughout North America and Europe (2,4). The earliest retrospective detection of O. ophidiicola in snakes was from 2000 (5). We report the earliest known confirmed cases of ophidiomycosis in free-living snakes in the United States, dating back to 1945.

We investigated the historical occurrence of ophidiomycosis in snakes in the United States by examining specimens preserved in formalin or ethanol at the University of Wisconsin Zoological Museum (UWZM; Madison, WI, USA) and Morehead State University Museum Collection (Morehead, KY, USA). We visually examined 524 specimens representing 30 snake species from 19 states in the eastern United States collected during 1900–2012 (Appendix 1, https://wwwnc.cdc.gov/EID/article/27/7/20-4864-App1.xlsx). To reduce risk for cross-contamination, we first examined snakes for clinical signs of ophidiomycosis within the glass jars in which they were stored. When specimens were removed from the jars for sampling, new gloves were worn to handle...
