ABSTRACT

A half-duplex relay station (RS)-based cellular system deployment is considered, where multiple base stations (BS) cooperate in the BS-RS in-band transmission for the downlink. The duration of the relay-receive and the relay-transmit phases are fixed beforehand, so that the interference induced by other cells is stationary during a transmission interval. With the optimization of the precoders and powers allocated to the wireless backhaul (relay-receive phase) and to the RS-MS access (relay-transmit phase), it is possible to exploit the benefits of network-MIMO (N-MIMO) along with combating the pathloss and shadowing effects thanks to the RSs. Consequently, an appealing significant enhanced spectral efficiency, power efficiency and coverage homogeneity are obtained. Results are benchmarked to the case where the relay phases are optimized.

1. INTRODUCTION

With the advent of new sophisticated terminals and bandwidth-demanding services, system designers are pushed towards the challenge of enhancing system spectral efficiency and providing homogeneous coverage for wireless networks. Next generation standards are already considering that conventional paradigms need to be rethought. In this respect, mature enabling technologies (like MIMO) are considered an integral part of the system, while other (like RS-based deployments and coordinated BS transmissions, or Network-MIMO) are part of ambitious study items. Leveraging on the advantages offered by the joint use of all these techniques is a challenge faced by IEEE 802.16m [1] and LTE-A.

While implementation details of full-duplex RS are under investigation, relay-based enhancements in standards consider half-duplex relay operation, which incur a rate penalty as they require at least two timeslots to relay a message from source to destination [2][3]. It is therefore crucial to enhance the capacity of the in-band wireless backhaul between source and relay (in our case, the BS–RS link) to increase the information rate. One of the solutions usually assumed is that RSs are placed in specifically planned positions above roof-top or in lampposts, ensuring line-of-sight (LOS) conditions in the BS–RS link, and hence reducing the pathloss and shadowing effects. However, the price to pay is twofold: the likely LOS propagating conditions also to other-cell BSs (which will inject harmful interference) and the rank deficiency of the spatial channel when both BS and RS are equipped with multiple antennas. Both effects are detrimental to MIMO channel gains [4][5].

In this respect, N-MIMO seems especially suited to address in-band backhauling in relay transmissions for the downlink [6]. While coordination may be seen as an efficient way to combat the interference from neighbor cells, it also creates a virtual MIMO broadcast channel whose number of degrees of freedom is boosted (if compared to a conventional single-user MIMO under TDMA) and is hardly affected by the rank deficiency of single-user MIMO channels in LOS.

It has been observed that N-MIMO based on zero-forcing (BD–ZF) performs closely to dirty-paper coding [6] but, although its simplicity, it requires accurate channel knowledge from all involved links. However, N-MIMO is again appropriate for our problem thanks to the long channel coherence time of BS–RS links.

An additional way to improve the efficiency of relay transmissions is by optimizing the duration of the relay-receive and the relay-transmit phases [2][3]. In [13], we observed that the joint optimization of coordinated BS-RS links (through N-MIMO) and transmit duration phases brings large benefits. This approach is however not convenient when considering multiple coordinated cells: if each group of coordinated cells adapts the duration of the transmission independently, the interference power observed in each transmission slot may be time-varying, a harsh and undesirable situation for the cellular system.

The evaluation of the N-MIMO with in-band relaying for fixed duration of relay phases motivates this study. As compared to [15], the problem formulation is a particular case whose solution has a significantly reduced complexity: the number of variables to be optimized turns out to be independent on the number of transmission modes, thus making it easily amenable to multicarrier systems.

2. SYSTEM ASSUMPTIONS

Our system definition is based on the following practical assumptions:

1. The number of antennas at BS, RS and MS is $n_B$, $n_R$ and $n_M$ respectively, so MIMO performance gains are captured.
2. Perfect channel state information at the transmitter side (CSIT) is available at the BSs, so per-mode power loading is possible at the BS-RS link.
3. RSs are time half-duplexed terminals operating under Decode-and-Forward (DF). That is a suitable coding approach for BS-RS links, where high SNR is expected if LOS propagation is met [7].
4. Mobile stations (MSs) do not process the signals transmitted by the BS, only those transmitted by the RS. In other words simple forwarding relaying is assumed.
5. RS transmissions are not coordinated in the way BS transmissions are. Their transmissions are either interfered (if multiple RSs transmit simultaneously) or orthogonalized (if allocating one time slot per RS transmission). In the later case, the number of time slots is denoted by $F$.
3. NETWORK-MIMO IN RELAY TRANSMISSION

3.1. Signal model on the first hop

We shall adopt a downlink transmission setup where BS coordinate their transmissions and are assisted by RS to transmit messages to MSs. Each MS is associated to a single BS. All BSs transmit on a fixed fraction of time \( \alpha_t \) on the first hop to the RSs following a N-MIMO strategy based on BD-ZF [6][9] (Figure 1), which is appropriate for BS-RS links in LOS conditions (MMSE precoding provides improved performance only at low SNR [10]).

The signal transmitted by all \( N_B \) B antennas is given by

\[
\mathbf{x} = \sum_{j=1}^N \mathbf{Q}_j \mathbf{p}_j \in \mathbb{C}^{N_B \times 1}
\]

where \( \mathbf{Q}_j \) is the symbol stream with \( j \)-th RS and \( \mathbf{p}_j \) is its associated precoding matrix. We adopt a conventional BD-ZF precoding [6] defined by three matrices,

\[
\mathbf{Q}_j = \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j^T
\]

where \( \mathbf{P}_j \) is a diagonal matrix describing the power allocated per symbol stream \( \mathbf{p}_j \), while \( \mathbf{V}_j \) is the \( B \times n_R \)BD-ZF precoding matrix. By virtue of the ZF precoding, the signal received by the \( i \)-th RS is affected by the \( n_R \) rows of the channel matrix \( \mathbf{H}_i \), (containing the channel gains between the transmitting antennas at the BSs and its receiving antennas):

\[
\mathbf{y}_i = \mathbf{H}_i \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j^T \mathbf{b}_j + \sum_{j'=1,j\neq j'}^N \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j^T \mathbf{b}_j + \mathbf{n}_i \in \mathbb{C}^{N_R \times 1}
\]

where \( \mathbf{n}_i \) denotes the number of symbol streams associated to the \( i \)-th RS. Regarding matrix \( \mathbf{W}_i \), if we decide to maximize the transmission rate, its optimal design has been recently derived in [15] when individual power constraints per BS are considered. However, the improvement over SVD-based precoding is modest at the expenses of increasing the computational complexity. Consequently, we define \( \mathbf{W}_i \) as the matrix containing the \( m_i \) right singular vectors of \( \mathbf{H}_i \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j^T \) associated to the largest singular vectors.

The BD-ZF precoder design requires \( \mathbf{V}_j \in \text{kernel}(\mathbf{H}_i) \), where:

\[
\mathbf{H}_i = \begin{bmatrix} \mathbf{H}_1^T & \cdots & \mathbf{H}_1^T \mathbf{H}_1^T & \cdots & \mathbf{H}_R^T \end{bmatrix}
\]

The existence of the kernel requires \( B \cdot n_R > (R-1) \cdot n_B \), and hence:

\[
\text{rank}(\mathbf{H}_i \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j) \leq \min(n_B, B \cdot n_R - (R-1) \cdot n_B)
\]

Additionally, symbol decidability at the receivers requires

\[
s_i \leq B \cdot n_R \quad \text{where} \quad s_i = \text{rank}(\mathbf{H}_i \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j) \leq \text{rank}(\mathbf{H}_i) \quad i = 1, \ldots, R
\]

It must be remarked that in the eventual case the \( i \)-th RS observes all coordinated BSs in LOS (hence BS-RS link channels are rank deficient) the rank of \( \mathbf{H}_i \) grows up to full-ranks rank if channels to the \( B \) BSs are linearly independent.

Once \( \mathbf{W}_i \) have been selected, the achievable rate for messages intended to the \( i \)-th RS becomes,

\[
r_i = \log_2 \left[ 1 + \mathbf{S}_q \mathbf{P}_q \right] - \sum_{j=1}^N \log_2 \left( 1 + s_j \cdot p_j \right)
\]

where \( \mathbf{S}_q = \text{diag}(s_1, \ldots, s_q) \) contains the singular values of \( N_i \mathbf{H}_i \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j \) (being \( N_i \) the correlation matrix of the noise plus external interference) and \( \mathbf{P}_q = \text{diag}(p_1, \ldots, p_q) \).

The total power transmitted by the \( k \)-th BS is given by:

\[
P_k^i = tr \left[ \mathbf{E} [\mathbf{x}_i \mathbf{x}_i^H] \right] = \sum_{j=1}^N \mathbf{W}_j \mathbf{P}_j^T \mathbf{W}_j^H
\]

where \( \mathbf{x}_i \) is the signal transmitted by the \( k \)-th BS, \( \mathbf{W}_j \) contains the \( n_B \) rows of \( \mathbf{V}_j \mathbf{W}_j \mathbf{P}_j \) used by the \( k \)-th BS in the transmission of message to the \( i \)-th RS and \( \mathbf{W}_j^H \) is the \( j \)-th column of \( \mathbf{W}_j \). Moreover, the power transmitted by \( i \)-th antenna at the \( k \)-th BS is:

\[
P_i^k = E \left[ |\mathbf{w}_i^H \mathbf{x}_i|^2 \right] = \mathbf{w}_i^H \mathbf{P}_q \mathbf{w}_i
\]

where \( \mathbf{x}_i \) is the \( i \)-th element of \( \mathbf{x}_i \), and \( \mathbf{w}_i \) is the \( i \)-th column of \( \mathbf{W}_j \).

3.2. Signal model on the second hop

On the second hop, each RS transmits to its associated MS on a fixed fraction of time \( \alpha_q \) on the second hop, which may be split over \( F \) time slots (being \( F \) an integer multiple of \( R \)) of durations \( \alpha_{q1}, \ldots, \alpha_{qF} \) (see Figure 1). On each time slot, RF relays can transmit. In this way we reduce interference at the expenses of some loss in spectral efficiency.

As we are assuming no coordination among RSs and simple receivers at the MS, only single user MIMO transmissions can be appointed. The achievable rate for each RS-MS link, \( r_{q} \), follows the conventional MIMO capacity expression, affected by the presence of interference from other RS transmissions:

\[
r_{q} = \log_2 \left[ 1 + \frac{P_{q}}{\sigma^2} \mathbf{h}_q^H \mathbf{h}_q \right] - \sum_{j=1}^F \frac{P_{q}}{\sigma^2} \mathbf{h}_q^H \mathbf{h}_j
\]

where \( i = 1, \ldots, R ; q = 1, \ldots, F ; r_{q} \) denotes the rate in the \( i \)-th RS-MS link, which has been scheduled in timeslot \( q \); \( P_{q} \) is the power transmitted by the \( i \)-th RS in the \( q \)-th time slot to its MS and \( P_{q}^i \) defines the power transmitted by the \( j \)-th BS on the same time slot.}

When \( F=R \) (interference is avoided at RS transmissions), the best solution is setting \( P_{q}^i \) to the maximum power on each RS (\( P_{q}^i_{\text{max}} \)). Otherwise, when \( F<R \) we can adapt the power transmitted by each BS in such a way that the interference generated to other MS on \( q \)-th time slot is reduced, and hence \( r_{q} \) increases. To that end, we propose the following optimization for each \( q \)-th time slot:

\[
\min_{P_{q}^i} f(r_{1q}, \ldots, r_{Kq}) \quad \text{s.t.} \quad P_{q}^i \geq 0 \quad i = 1, \ldots, R
\]
a problem that is not convex in $P_u^*$ even for concave target functions $f_i$. However, it is sure that there is a better option than all RSs transmitting at $P_u^*$ which can be obtained by applying interior point methods [11] initializing $P_u$ with $P_u^*$. To preserve information flow through RSs, the rate at the $i$-th MS served by the $i$-th RS is constrained by the minimum of rates in both hobs:

$$r_i \leq \min(\alpha_i r_i, \alpha_{2i} r_{2i}) \leq 0 \quad i=1, \ldots, R$$

where $i = 1, \ldots, R; \quad q = 1, \ldots, F$; and $r_{2i}$ is the rate in the second hop obtained from the optimization in (9). Equation (10) can also be written as two simultaneous inequalities:

$$\begin{align*}
\alpha_i \sum_{p=1}^{n} \log_2 (1 + s_i p_i) &\geq r_i \quad \alpha_{2i} r_{2i} \geq r_i
\end{align*}$$

3.3. WSR-based resource allocation

We allocate the resources based on the maximization of the weighted sum-rate (WSR) criterion that allows adding certain QoS over the served users depending on priorities $\rho_i$:

$$\begin{align*}
\min_{\{\rho_i\}_{i=1}^R} \sum_i \rho_i r_i
\end{align*}$$

s.t.

$$r_k - \alpha_k r_k \log_2 (1 + s_i p_i) \leq 0 \quad i = 1, \ldots, R$$

$(P_{WSR})$:

$$\begin{align*}
\min_{\{\rho_i\}_{i=1}^R} \sum_i \rho_i r_i - P_{\text{max}} \quad k = 1, \ldots, B
\end{align*}$$

Equation (11) can also be obtained from the optimization in (9). Equation (10) can also be written as two simultaneous inequalities:

$$\begin{align*}
\alpha_i \sum_{p=1}^{n} \log_2 (1 + s_i p_i) &\geq r_i \\
\alpha_{2i} r_{2i} &\geq r_i
\end{align*}$$

The values of $\lambda^*$ are calculated using algorithm in Table 1, which is based on the bisection method for $\lambda^*$, and the ellipsoid method [14] for $\lambda^*$. The subgradients required to update them are:

$$\begin{align*}
d_i = \sum_{p=1}^{n} \rho_i p_i - P_{\text{max}}, \quad \frac{\alpha_i}{\ln 2} \sum_{p=1}^{n} \log_2 (1 + s_i p_i) - \alpha_{2i} r_{2i}
\end{align*}$$

4. EVALUATION AND RESULTS

The evaluation of the proposed approach is done on a radio access network based on 802.16m specifications [11] at the 2.6 GHz band and 20 MHz bandwidth. Channel models adopted are outdoor-to-outdoor obtained from [12]. We assume LOS conditions for all BS-RS links and distance-dependent LOS/NLOS condition for BS-MS and RS-MS links. 3 BSs and a total of 6 RSs are deployed. On each scenario, 6 MSs are dropped, each attached to a different RS. All RSs are at the same distance to their associated BS, equal to 60% of the cell radius (experimentally found as the best position for the case with $F=1$). Transmit powers are 40 dBm and 30 dBm, and antenna gains of 10.6 dBi and 5 dBi, for BS and RS respectively. Noise spectral density is -174 dBm/Hz. The number of antennas is $n_B=4$ at the BS, $n_R=2$ at the RS and $n_d=1$ at the MS, and thus $\delta_i = 2$.

It has been observed that users close to the BS are not benefited from the RS assistance. While we recognize that a practical scheduling scheme should consider splitting the population between those close-to and those far-from their serving BS, the topic is deferred to a forthcoming study. In order to include only those users benefiting from the presence of relays, in our evaluations users are uniformly placed beyond 35% of the cell radius. The cell arrangement is shown in Figure 1.

Two fundamental measures are adopted: cellular spectral efficiency ($S_c$), as the sum rate of $R$ users averaged over many deployments, and outage rate ($r_{\text{out}}$), as the peak achievable rate of the percentile worst users in the cell over many deployments. Both capture most of the benefits offered by coordination of BS and relay-based transmission.

Table 1. Algorithm solving $P_{WSR}$ for $B=3$ and $R=6$

| Step | Description |
|------|-------------|
| 1. | Initialize: $\lambda^*_1, \lambda^*_2, \lambda^*_3, \lambda^*_4, \lambda^*_5$ |
| 2. | while $|\lambda^*_1 - \lambda^*_2| > \epsilon$ do |
| 3. | $\lambda_1 = \frac{1}{2}(\lambda^*_1 + \lambda^*_2)$ |
| 4. | while $|\lambda^*_2 - \lambda^*_3| > \epsilon$ do |
| 5. | $\lambda_2 = \frac{1}{2}(\lambda^*_2 + \lambda^*_3)$ |
| 6. | while $|\lambda^*_3 - \lambda^*_4| > \epsilon$ do |
| 7. | $\lambda_3 = \frac{1}{2}(\lambda^*_3 + \lambda^*_4)$ |
| 8. | $[\lambda_1, \lambda_2, \lambda_3] = \text{Ellipsoid method}$ |
| 9. | Initialize $\lambda_1, \lambda_2, \lambda_3$ |
| 10. | Repeat |
| 11. | - Compute $p_i \left(\lambda_1, \lambda_2, \lambda_3\right)$ given by (13) |
| 12. | - Compute subgradient $\hat{\delta}_i$ given by (14) |
| 13. | - Update $\hat{\lambda}_i, \ldots, \hat{\lambda}_r$ [14] |
| 14. | until convergence |
| 15. | if $d_i < 0$, $\lambda^*_2 = \lambda_i$, else $\lambda^*_2 = \lambda_i$ |
| 16. | end while |
| 17. | if $d_i < 0$, $\lambda^*_3 = \lambda_2$, else $\lambda^*_3 = \lambda_2$ |
| 18. | end while |
| 19. | if $d_i < 0$, $\lambda^*_4 = \lambda_3$, else $\lambda^*_4 = \lambda_3$ |
| 20. | end while |

The duration of time slot $\alpha$ used in the simulations is based on the results obtained in [13], where it is shown that the optimum $\alpha$ in terms of spectral efficiency is a random variable that depends on the particular scenario and the target function to be maximized. It
was observed that its mean value is lower for $F=6$ than for $F=1$. Fixing the position of the RS at 60% of the cell radius, the mean value of the optimum $\alpha_1$ does not exhibit an appreciable variation with higher cell radius for $F=6$ (no interference in the second hop). For $F=1$ it increases with cell radius due to the fact that interference in the second hop is reduced with higher cell radius while rate losses in the BS-RS link are larger due to increased distance. However the main variation of $\alpha$ values is given by the objective function to be maximized. When using WSR and the weights are inversely proportional to the rates in the second hop (that is $\mu_s=1/r_{\text{out}}$ in order to avoid unfair service to deprived users) lower values of $\alpha_1$ are observed than for SR.

In a first study, the optimal solution to the (P WSR) in (12) is evaluated for the SR and the WSR, over 1000 random user deployments with $F=1$. The objective function used in (9) is the product of rates because it achieves an enhanced $r_{\text{out}}$ and allows the design of a more fair service in the second hop, although other criteria could also be used. Figure 2 displays $r_{\text{out}}$ vs. $S_1$ for cell radii of 500, 750 and 1000 m adopting different transmission strategies: N-MIMO with relay-assistance (Relayed N-MIMO $\alpha_i=0.2$ and N- MIMO $\alpha_i=0.3$ in legend), N-MIMO with relay-assistance and dynamic optimized $\alpha$ (Relayed N-MIMO), N-MIMO direct transmission (N-MIMO) and relayed transmissions with uncoordinated beamforming precoding at the BS (BF-TDMA), both under the SR criterion. In this later case, each BS serves its associated RS under round-robin TDMA. Figure 2 shows significant gains in terms of $S_1$ by N-MIMO strategies as compared to BF-TDMA, remarkably boosted by the use of relays. Moreover, when $\alpha$ is optimized, the gains in terms of spectral efficiency and outage rate are comparable with the fixed $\alpha$ case. This confirms the possibility of having systems gains even if the duration of phases is kept fixed over the time

\[ F \times \text{max} \]

where, due to half duplexing of the RS:

\[ P = \alpha_1 \sum_{i=1}^{R} P_i + \alpha_2 \sum_{i=1}^{R} P_i^R \]

Figure 3 shows the cumulative density function (cdf) of $\xi_f$ when WSR or SR criteria, both with $F=1$, are adopted. We can see that by optimizing the transmitting power at RSs, $\xi_f$ is nearly doubled: achievable user’s bit rate are higher and the system power consumption is lower. Moreover, when compared to direct N-MIMO transmissions, the power efficiency of relay transmissions is nearly fourfold as a consequence of the enhanced spectral efficiency and the fact that RSs transmit lower power than BSs.

5. CONCLUSIONS AND OUTLOOK

Optimal resource allocation algorithms for QoS-constrained relay-assisted cellular systems have been proposed, where cooperation between BS is appointed and the duration of the relaying phases is fixed. Results show that optimizing the duration is not critical, and still large gains both in terms of spectral efficiency and outage rate are obtained. This observation facilitates the adoption of relay transmissions in next-generation wireless systems, as this guarantees the predictability of other cell-clusters interference within transmission frames. Further work is oriented to study modulation-constrained resource allocation, user’s grouping and scheduling strategies and coordination of transmissions between cell clusters.

6. APPENDIX

The Lagrangian function of (P WSR) in equation (12) becomes:

\[ L = \sum_{i=1}^{R} \mu_i r_i + \]

\[ + \sum_{k=1}^{N} \sum_{j=1}^{K} \varphi_k \theta_k^j - P_{\text{max}} \]

\[ + \sum_{i=1}^{R} \eta_i r_i - \alpha \sum_{i=1}^{R} \log_2(1 + s_i x_i p_i) \]

(15)

where $\mu_i$, $\varphi_k$, and $\eta_i$ denote the Lagrange multipliers or dual variables associated to the max-power per BS, Shannon bit rate and max-rate constraints, respectively. Finally, $\eta_i$, $\varphi_k$ are the Lagrange multipliers needed for having positive values of bitrate and allocated power at BSs. The conditions to minimize the Lagrangian as a function of the bitrate $r_i$ and allocated power $P_i$ become,

\[ \xi_f = \frac{1}{R} \sum_{i=1}^{R} r_i^f \quad \text{(bps/Hz/Watt)} \]
Since we are interested in attaining the maximum rate but using the minimum required power, we transform the bitrate inequalities in the first hop into max-power constraints. In this regard, let us define the maximum power used in the first hop for the i-th RS as the solution of the optimization problem, 

\[ \begin{align*}
\min_{\{\mu_i\}} & \quad \frac{1}{\ln 2} \sum_{j=1}^{\infty} p_j \\
\text{s.t.} & \quad \begin{cases}
\alpha_j \phi_j - \alpha_i \sum_{j=1}^{\infty} \log_2 (1 + s_{ij}^2 p_j) \leq 0 \\
p_j \leq 0
\end{cases}
\end{align*} \]  

The power allocation turns out to be, 

\[ p_j(\alpha_i) = \left( \frac{\alpha_i \mu_j}{\ln 2} - 1 - s_{ij}^2 \right), \quad \alpha_i = 2 \left( \frac{\gamma_i - \alpha_i \sum_{j=1}^{\infty} \log_2 (1 + s_{ij}^2 p_j)}{\ln 2} \right) \]  

and the total power employed for the transmission to the i-th RS is 

\[ P_{2i} = \sum_{j=1}^{\infty} p_j(\alpha_i) \]  

Now, reformulate the problem (PWSR) in (12) taking into account the max-power per stream when we are limited by the bitrate of the second hop (19):

\[ \begin{align*}
\min_{\{\mu_i\}} & \quad - \sum_{i=1}^{R_i} \mu_i \\
\text{s.t.} & \quad \begin{cases}
\gamma_i - \alpha_i \sum_{j=1}^{\infty} \log_2 (1 + s_{ij}^2 p_j) \leq 0 \\
\lambda_i : \sum_{j=1}^{\infty} p_j \delta_j - P_{2i} \leq 0 \\
\eta_i : \gamma_i - \alpha_i \sum_{j=1}^{\infty} \log_2 (1 + s_{ij}^2 p_j) \leq 0
\end{cases}
\end{align*} \]  

Notice that we have included the Lagrange multipliers \( \lambda_i \) instead of \( \gamma_i \) in (15) with the proper power constraint \( P_{2i} \) as obtained from (19). The conditions to optimize (20) become, 

\[ \begin{align*}
\gamma_i = \mu_i, \quad \eta_i = 0, \quad \phi_i = 0 \\
p_j(\lambda_i, \tilde{\lambda}_i) = \alpha_i \left( \frac{\mu_j}{\ln 2} - 1 - s_{ij}^2 \right)
\end{align*} \]  

Let us define the dual function of \( \{P_{WSR}\} \) taking into account its Lagrangian and the solution in (21), 

\[ g(\lambda_i, \tilde{\lambda}_i) = \sum_{i=1}^{R_i} \mu_i \alpha_i \sum_{j=1}^{\infty} \log_2 (1 + s_{ij}^2 p_j) + \sum_{k=1}^{\infty} \lambda_k d_k + \sum_{j=1}^{\infty} \tilde{\lambda}_j d_j \]  

\[ d_i = \sum_{j=1}^{\infty} \sum_{j=1}^{\infty} p_j s_{ij}^2 \delta_j - P_{2i}, \quad \tilde{d}_i = \sum_{j=1}^{\infty} p_j - P_{2i} \]  

The optimal values of the Lagrange multipliers are obtained by maximizing the dual function, 

\[ \begin{align*}
\max \quad & g(\lambda_i, \tilde{\lambda}_i) \\
\text{s.t.} & \quad \lambda_i \geq 0 \quad \forall k, \quad \tilde{\lambda}_i \geq 0 \quad \forall i
\end{align*} \]  

Since (PWSR) is convex, gradient-type search is guaranteed to converge to the global optimum of (23). Search directions given by \( d_i, \tilde{d}_i \) in (22) coincide with the subgradient, [14]. This suggests that if a given constraint is exceeded the associated Lagrange multiplier should be increased, or decreased otherwise. In this respect, we can avoid calculating \( P_{2i} \) in (19) by defining the gradient in equation (14) that also accounts for the maximum rate.

The algorithm presented in Table I compiles the method, and it is able to provide the optimal values for \( \lambda_i, \tilde{\lambda}_i \) with a polynomial complexity.
