Laboratorial Aspects of Cytolytic Vaginosis and Vulvovaginal Candidiasis as a Key for Accurate Diagnosis: A Pilot Study

Aspectos laboratoriais da vaginose citolítica e candidíase vulvovaginal como uma chave para o diagnóstico preciso: Um estudo piloto

Abstract

Objective To identify clinical, microscopic, and biochemical characteristics that differentiate cytolytic vaginosis (CV) from vulvovaginal candidiasis (VVC).

Methods The present cross-sectional study analyzed the vaginal contents of 24 non-pregnant women aged 18 to 42 years who were attended at the Genital Infections Clinic at Centro de Atenção Integral à Saúde da Mulher da Universidade Estadual de Campinas (CAISM-UNICAMP). They were diagnosed either with (CV = 8, VVC = 8) or without vulvovaginitis or vaginal dysbiosis (controls). The socio-demographic, clinical, and gynecological data were obtained from a detailed patient interview. Samples of the vaginal contents were collected for analysis of vaginal pH, gram stain, and specific fungal culture. The Kruskal-Wallis and Fisher exact tests were used to compare the differences between the groups. Odds ratios were used to compare the categorical variables. The significance level was considered at \( p < 0.05 \).

Results Both women with CV and VVC had a lumpy vaginal discharge (\( p = 0.002 \)) and vaginal hyperemia (\( p = 0.001 \)), compared with controls. The inflammatory process was more intense in the VVC group (\( p = 0.001 \)). In the CV group, there was statistical significance for the lactobacillus amount (\( p = 0.006 \)), vaginal epithelium lysis (\( p = 0.001 \)), and vaginal pH (\( p = 0.0002 \)).

Conclusion Cytolytic vaginosis and VVC diagnoses rarely differ on clinical characteristics but have different laboratorial findings. The present study highlights the importance of conducting an accurate investigation through laboratory tests rather than clinical criteria to avoid misdiagnosis.
Laboratorial Aspects of Cytolytic Vaginosis and Vulvovaginal Candidiasis  Sanches et al. 635

text

**Introduction**

Vulvovaginal candidiasis (VVC) infection caused by the *Candida* species affects millions of women every year and is considered the second most common vaginitis among women after bacterial vaginosis. It is estimated that ~10 to 15% of asymptomatic women are colonized by *Candida* sp and 70 to 75% of women of reproductive age experience at least one acute episode during their life. About 50% of these will have a second episode, and 5 to 10% will develop the recurrent form. Vulvovaginal candidiasis gives rise to much discomfort in many patients, poses a threatening problem to clinicians, and generates considerable direct and indirect economic costs associated with medication and healthcare visits, representing a cost estimate of $2.84 billion in the United States alone. Most women will experience only one or two episodes of VVC, but there is a large, albeit poorly defined, subset that experiences multiple recurrences. Among all cases of VVC, *C. albicans* is the most common species identified among women, representing 80 to 90% of the cases, followed by non- *C. albicans* species, usually *Candida glabrata*. The VVC manifests itself as an inflammatory process, which, depending on the degree of local inflammation, has variable symptom intensity and is commonly misidentified as cytolytic vaginosis (CV), leading to inadequate treatment. Cytolytic vaginosis is characterized by symptoms that are very similar to those of VVC, but the laboratorial findings may be quite different. The CV criteria proposed in 1991 by Cibele and Cibley are: absence of *Trichomonas*, *Gardinerella*, or *Candida* on wet smear, an increased number of lactobacilli, paucity of leukocytes, high vaginal epithelium cytosis, presence of a lumpy discharge, and vaginal pH between 3.5 and 4.5. Clinical characteristics of women with VVC include white flocculent vaginal discharge along with vulvovaginal pruritus, which may present with vulvovaginal pain and fissures. An intense inflammatory process can be observed in the vulva and/or the vagina due to the aggression on the epithelium caused by fungi. Both present with symptomatology that is accentuated in the premenstrual period. Vulvovaginal burning is usually more frequent in CV, while vulvovaginal pruritus is a common symptom from women with VVC. However, women can have either symptom or present difficulty when reporting their symptoms to clinicians, misleading the diagnosis and, as a consequence, the treatment. The identification of clinical and microscopic characteristics that can differentiate CV from VVC in the outpatient setting is essential in improving the accuracy of the diagnosis, treatment, and management for women with vaginal discharge complaints. Thus, the aim of the present study was to compare the clinical and laboratorial findings of women with VVC and VVC to define more accurate criteria to differentiate these two conditions.

**Methods**

**Selection of Subjects and Sample Collection**

In total, 42 sexually active women from 18 to 45 years old who attended the Genital Infections Outpatient Clinic of Universidade Estadual de Campinas from November 2016 to March 2017 were invited to participate in the study. Following the clinical routine of the hospital, all patients were submitted to a detailed anamnesis and gynecological
examination. Using a sterile Dacron swab, material from the vaginal wall was collected to identify cervicovaginal diseases and to verify vaginal ecosystem conditions. Women diagnosed with endocervicitis, bacterial vaginosis, trichomoniasis, and mixed infections were ruled out. After checking for eligibility, eight women diagnosed with VVC, eight with CV and eight women with normal vulvovaginal flora and clinical characteristics (control group) were included in the study. All of the women selected were interviewed about their clinical complaints and signed the informed consent form. The local ethics committee board approved the study (process number is CAAE: 60648016.8.0000.5404).

Measurement of Vaginal pH
This test was performed with a MERCK colorimetric tape (Merck & Co., Inc., Kenilworth, NJ, USA) (ranging from 4.0–7.0 with variation intervals of 0.3) by placing the tape in the middle third of the vaginal wall for one minute and avoiding contact with the cervical mucus. After removal, the vaginal pH at that moment was checked according to the scale.

Bacterioscopy by Gram Staining and Wet Mount Microscopy
A sample of the vaginal contents was spread on a microscope slide and left to dry for Gram staining. It was characterized by the type of vaginal microbiota (Lactobacillus species predominance and/or other types of bacteria), the cellularity in the smear, bacterial morphology, the leukocytes, the presence or absence of inflammation (absent, 1–4, or > 4), and identifying pathogens as fungi. Also, the presence of hyphae was confirmed by visualization of the fungi on wet mount light microscopy of a vaginal sample. The diagnosis of bacterial vaginosis was based on the Nugent criteria.9,10

Fungal Culture
A sample of the vaginal contents was collected from the middle third of the vaginal wall with a sterile swab and sown in Sabouraud’s growth medium, which was sent to the Clinical Pathology Laboratory of the Clinical Hospital (HC) (microbiology laboratory), where they were processed, analyzed, and released into the hospital system.

Statistical Analysis
The Fisher exact test and odds ratio were used to compare the categorical variables, and Kruskal-Wallis compared continuous variables with abnormal distribution among the three groups studied. The significance level adopted for the statistical tests was 5% (p < 0.05), with a study power calculated to 80%. The SAS System for Windows version 9.2 (SAS Institute Inc, Cary, NC, USA) was used for the statistical analysis.

Results
Regarding the sociodemographic and gynecological characteristics, no statistically significant differences were observed among the three groups (►Table 1).

Table 1 Sociodemographic and medical characteristics of the study subjects

| Characteristics                              | VVC   | CV    | nl    | p-value* |
|----------------------------------------------|-------|-------|-------|----------|
| Age in years **                            | 36    | 34.75 | 31.13 | 0.379    |

|                                              | Yes   | 12.5% (1) | 0%   | 0.125    |

Abbreviations: CV: cytolytic vaginosis; nl, control group; VVC: vulvovaginal candidiasis.
*p-value according to the Kruskal-Wallis test for comparison of values among the 3 groups, followed by Dunn test for multiple comparisons (p < 0.05).
**Age average per group.
The frequency of vaginal hyperemia in VVC and CV was higher than in the control group, as well as the pasty discharge aspect for both conditions ($p = 0.0002$). The statistical analysis showed the same significant variables when comparing the categorical variables by groups (Table 2), confirming even more precisely the results presented.

We can observe that the most prevalent complaints by the patients with VVC and CV are the existence and quantity of vaginal discharge, accompanied by dyspareunia (supplementary material 1). Vaginal itching and burning are reported by both groups, but itching and vulvar hyperemia are more related to VVC. Through the laboratorial characterizations, it was possible to confirm the diagnosis. Through the measurement of vaginal pH, it was demonstrated that the pH was lower in CV (3.8–4.0) and higher in VVC (4.5–4.7) (Table 3).

In women with VVC, CV, and controls, the vaginal microflora was primarily composed of Gram-positive lactobacilli. The lysis of the vaginal epithelium and the number of lactobacilli were significantly represented in the CV group, and the presence of inflammatory process was observed in the VVC group (Table 3). The vaginal bacterioscopy of the groups studied is represented by Fig. 1. The presence of inflammatory process and Candida spp blastospores as well as of hyphae characterizing VVC are shown in Fig. 1A and 1B. Intense lysis and increased number of lactobacilli, absence of inflammatory process, and visualization of nude nuclei, complementary to patients’ complaints, accurately indicate CV (Fig. 1C).

The integrity of the decayed epithelial cells, the absence of inflammatory process, and the normal number of lactobacilli reflect the quality of the vaginal environment and the maintenance of the basic conditions for the stability of the vagina microenvironment and is represented by Fig. 1D. All women in the VVC group presented positive fungal culture.

Discussion

The vaginal discharge complaint is one of the main factors that lead women to gynecological consultation, but it is often not so easy for the physician to make a correct diagnosis. In regard to signs and symptoms, CV is very similar to VVC. Most of the women who have CV are incorrectly diagnosed with complicated VVC refractory to treatment and, in some cases, are referenced for psychiatric treatment.11,14 Due to the fact that clinical presentation in CV and VVC is similar, a

high level of suspicion is necessary for a correct diagnosis, especially if there is illness with a history of recurrence to specialists from several areas, symptomatology systematically refractory to various antifungal/antibiotic agents, or a diagnosis of complicated candidiasis.\textsuperscript{11,14–16} In addition to VVC, there is another pathology whose signs and symptoms are similar to CV: Döderlein lactobacillus. In this situation, there is an increase in the size of lactobacilli, which is also accompanied by a more modest increase in bacterial load. However, there is no cellular cytolysis.\textsuperscript{17,18} Microscopic examination of vaginal discharge is the pillar of the differential diagnosis among these pathologies, which is particularly important since the treatment differs according to the entity in question.\textsuperscript{11,13,17,18} In view of this, a set of clinical and laboratorial criteria must be available that, when evaluated together during the gynecological examination, can provide the physician with support for an accurate diagnosis. First, when analyzing the sociodemographic variables, we did not find significant differences among the three groups studied. We only observed a higher frequency between the number of pregnancies and women with CV, but without statistical significance, similar to what had been previously reported.\textsuperscript{13} Regarding the clinical and pH characteristics, we found that factors such as vaginal discharge and vaginal hyperemia were more frequent in women with CV and VVC, when compared with the control group. The vaginal pH is significantly different between women with CV and VVC.\textsuperscript{10} Some species of lactobacilli, by action of different mechanisms, are able to maintain an acidic vaginal pH, with lactate being its main product. Acidic vaginal pH is essential for the protection of the vaginal epithelium against pathogenic microorganisms that develop best at basic pH.\textsuperscript{19,20} A study conducted by our research group found a higher concentration of L-lactate in women with cytolytic vaginosis.\textsuperscript{21} The exacerbated growth of lactobacilli leads to higher vaginal acidity due to the action of this lactate, and the increase of this acidity can be routinely detected in the outpatient clinic through vaginal pH tapes. The pH strip with more detailed variation of color, the use of markers for the presence of leukocytes (leukocyte esterase), or cell lysis presence of histamine or other lysis marker would be relevant. When evaluating Gram-stained vaginal smears, we observed a marked cellular lysis in all women with CV, associated with a large number of lactobacilli and an absence of polymorphonuclear cells. Similarly to these bacterioscopic results, it was found that lactobacilli overgrowth, increased cytolysis, and absence of polymorphonuclears in the cervical smears are factors associated with cytolytic vaginosis.\textsuperscript{13} However, these authors focused only on the morphological diagnosis by bacterioscopy, whereas in our study we also considered clinical signs and vaginal pH, which are criteria that, added to bacterioscopy, could increase the accuracy of the diagnosis of CV.

**Conclusion**

Cytolytic vaginosis has sufficient laboratorial characteristics to differentiate it from VVC. We can delineate bacterioscopic criteria capable of distinguishing CV and VVC: low pH, increased number of lactobacilli, and marked cytolysis, as well as absence of fungi and polymorphonuclear scarcity in the Gram smear. Such criteria are easy and applicable in clinical practice, providing a more detailed consultation, which may allow the patient to leave the consultation with an appropriate treatment. This study highlights the importance of conducting an accurate investigation through laboratory tests rather than clinical criteria to avoid misdiagnosis.
