Abstract

The two-component system VicRK and the orphan regulator CovR of Streptococcus mutans co-regulate a group of virulence genes associated with the synthesis of and interaction with extracellular polysaccharides of the biofilm matrix. Knockout mutants of vicK and covR display abnormal cell division and morphology phenotypes, although the gene function defects involved are as yet unknown. Using transcriptomic comparisons between parent strain UA159 with vicK (UAvic) or covR (UAcov) deletion mutants together with electrophoretic motility shift assays (EMSA), we identified genes directly regulated by both VicR and CovR with putative functions in cell wall/surface biogenesis, including gbpB, wapE, smaA, SMU.2146c, and lymM. Deletion mutants of genes regulated by VicR and CovR (wapE, lymM, smaA), or regulated only by VicR (SMU.2146c) or CovR (epsC) promoted significant alterations in biofilm formation, including increased fragility, defects in microcolony formation, and atypical cell morphology and/or chaining. Significant reductions in mureinolytic activity and/or increases in DNA release during growth were observed in knockout mutants of smaA, wapE, lymM, SMU.2146c and epsC, implying roles in cell wall biogenesis. WapE and lymM mutations also affected cell hydrophobicity and sensitivity to osmotic or oxidative stress. Finally, vicR, covR and VicRK/CovR-targets (gbpB, wapE, smaA, SMU.2146c, lymM, epsC) are up-regulated in UA159 during biofilm initiation, in a sucrose-dependent manner. These data support a model in which VicRK and CovR coordinate cell division and surface biogenesis with the extracellular synthesis of polysaccharides, a process apparently required for formation of structurally stable biofilms in the presence of sucrose.

Introduction

Streptococcus mutans is the major pathogen of dental caries and is commonly involved in bacteremia leading to infectious endocarditis [1–3]. The virulence of S. mutans lies in its ability to sense and adapt to environmental stresses during host colonization and biofilm formation (reviewed in [4]). This process involves systems for gene regulation designated two-component systems (TCS) [5]. A typical TCS comprises a histidine kinase (HK) membrane receptor which undergoes auto-phosphorylation in response to an environmental signal. The P-HK then transphosphorylates a cognate intracellular response regulator (RR), which in turn interacts with the regulatory regions of target genes. Cross-talk among TCS and with other regulatory systems also occurs [6]. The genome of S. mutans strain UA159 encodes 14 complete TCS [7,8], including the conserved TCS of Firmicutes designated VicRK (Vic, for Virulence control), also known as WalkR/K or Yyc/FG, which controls cell wall metabolism in several Gram-positive species [9,10]. Additionally, CovR (control of virulence; formerly named gobR), is an orphan RR in the UA159 genome, since covS, the gene encoding the cognate HK, has not been identified in S. mutans, although it is present in other streptococcal species [7,11]. In S. mutans, VicR and CovR directly regulate a panel of genes implicated in the synthesis of and interaction with extracellular polysaccharides [12–14], which are major components of the matrix of dental biofilms and essential for virulence (reviewed by [15]). Most of these genes are positively regulated by VicR [14,16], and/or repressed by CovR (gbfB/C/D, gfpC). Glucosyltransferases B, C, D (encoded by gbfB/C/D) catalyze the synthesis of glucan polysaccharides from sucrose. Glucan-binding proteins B (GbpB) and C (encoded by gbfB and gbpC respectively) have affinity for glucan and are implicated in biofilm formation, cell wall integrity, and virulence by mechanisms not fully understood (reviewed in [17]). Phenotypes of S. mutans covR knockout mutants include abnormal biofilm structure, cell aggregation and attenuated cariogenicity [18], while vicK mutants show defects in separation of daughter cells, and in sucrose-dependent biofilm formation [14]. The altered functions associated with covR/vicK-mutant phenotypes warrant further investigation [16]. In this study, we analyzed the transcriptomes of vicK and covR mutants to identify new gene targets implicated in cell wall/envelope biogenesis and biofilm growth. Gene expression analyses and phenotypic
characterization of knockout mutants of these genes indicate that CovR and VicRK regulate a set of genes implicated in cell wall biogenesis which are specifically activated during growth in the biofilm phase.

**Materials and Methods**

**Strains, Plasmids, Growth Conditions and Reagents**

Bacterial strains and plasmids used in this study are shown in Table 1. *Escherichia coli* was grown aerobically in Luria-Bertani medium supplemented as needed with ampicillin (100 μg/ml), erythromycin (200 μg/ml) or spectinomycin (200 μg/ml). *Streptococcus mutans* strains were routinely grown in Brain Heart Infusion (BHI) or Todd Hewit Broth (THB) as described previously [19]; when necessary erythromycin (erm, 10 μg/ml) and/or spectinomycin (spec, 300 μg/ml) were added to the media. Growth curves of the studied strains were performed as previously described [7], with minor modifications. PCR primers are shown in Table S1.

**Construction of Knockout Mutants**

Knockout strains were constructed by PCR ligation mutagenesis as described elsewhere [16,20] with minor modifications. Amplicons were generated with Taq DNA Polymerase High Fidelity (Invitrogen) from genomic DNA templates. The erythromycin resistance gene was amplified from plasmid pVA838. Amplicons obtained with primers E1/E2 and primer set P1/P2 for each gene were digested with AscI, purified using the StrataPrep Purification Kit (Stratagene), and ligated with T4 DNA ligase, according to the manufacturer’s protocol. Amplicons obtained with primers E1/E2 and respective primer set P3/P4 for each gene were digested with XhoI, purified and ligated. Ligation products were purified and used as templates in a PCR reaction with primers P1/P4, yielding mutant alleles in which target genes were disrupted by an erythromycin resistance cassette (ERM). Purified ERM-inactivated mutant alleles were transformed into *S. mutans* UA159 and transformants were confirmed as described previously [16]. To generate complemented strains, each mutant was transformed with plasmid pDL278 containing the intact copy of the respective deleted gene.

**Biomass Quantification of Biofilms**

To measure mature biofilm biomass formed during growth in media with sucrose, quantitative biofilm assays in polystyrene 96-well microtiter plates (round-bottom) were performed as previously described [21] with some modifications. Briefly, 500 μl of a BHI culture (A550nm 0.3) was transferred to 4.5 ml of fresh medium containing 0.1% sucrose. Aliquots (250 μl) were transferred in triplicate to polystyrene 96-well plates (BD Biosciences) and incubated in 10% CO2 for 8 and 18 h. After three washes with distilled water to remove planktonic or loosely attached cells, biofilms were stained with crystal violet for 30 min. Stain was eluted from biofilms with ethanol (30 min incubation), and absorbances of eluates were measured at A575 nm and expressed as amounts of biofilm biomass. Absorbances of cell suspensions (A550 nm) from each culture were measured as a control for planktonic growth. Similar assays were performed using Chemically Defined Medium [22,23] supplemented with 0.1% sucrose and Brucella broth supplemented with 5% blood and 0.1% sucrose. Amounts of biofilm biomass were expressed as means of three in-

dependent experiments performed in triplicate (2, 4, 18 h-biofilms) or six replicates (8 h-biofilms).

Electron Microscopic Analysis of Strains during Planktonic and Initial Phases of Biofilm Growth

The morphologies of UA159, knockout, and respective complemented strains were analyzed at mid-log phase of planktonic growth in the presence or absence of sucrose, and during initial phases of sucrose-dependent biofilm formation by scanning electron microscopy (SEM) as described elsewhere [16]. Briefly, overnight cultures of each strain were 100-fold diluted in fresh media and incubated until optical density (A\textsubscript{550 nm}) reached 0.3. Planktonic cells were harvested by centrifugation, washed three times with PBS and processed in microtubes for SEM analysis. To analyze cells in biofilms, 1.0 ml of cultures (A\textsubscript{550 nm} 0.3) were transferred to 24-well plate containing sterile glass slides. Plates were gently mixed and incubated for 2 and 4 h for biofilm formation. Biofilms were washed three times with PBS to remove non-adherent cells and processed for SEM analysis, as described previously [16]. Quantitative analyses of biofilm phenotypes used SEM digital images at 1,300\texttimes magnification of 32 pre-determined areas (97 to 63 μm²) of each sample equally distributed on each glass slide. Numbers of microcolonies and total covered surfaces per area were determined using ImageJ – Image Processing and Analysis software in Java (NIH, http://rsbweb.nih.gov/ij/index.html). Parametric analysis of variance (ANOVA) with post hoc Dunnott’s test was used to compare number of microcolonies and total covered areas between strains.

RNA Purification, Protein Extraction, Western and Northern Blotting

For RNA or protein extraction, cultures in BHI (A\textsubscript{550 nm} 0.3) were harvested by centrifugation (6000 x g, 4°C, 3 min), washed twice in cold saline, suspended in 220 μl 10 mM Tris, 1 mM EDTA, pH 8.0 (TE), and stored at −80°C until use. Mechanical disruption of cells was carried out with 0.16 g 0.1 mm diameter Zirconium Beads (Biospec) on a Mini-beadbeater (Biospec) at 4°C, 1 min, 4°C. Planktonic cells were harvested by centrifugation, washed three times with PBS and processed in microtubes for SEM analysis. To analyze cells in biofilms, 1.0 ml of cultures (A\textsubscript{550 nm} 0.3) were transferred to 24-well plate containing sterile glass slides. Plates were gently mixed and incubated for 2 and 4 h for biofilm formation. Biofilms were washed three times with PBS to remove non-adherent cells and processed for SEM analysis, as described previously [16]. Quantitative analyses of biofilm phenotypes used SEM digital images at 1,300\texttimes magnification of 32 pre-determined areas (97 to 63 μm²) of each sample equally distributed on each glass slide. Numbers of microcolonies and total covered surfaces per area were determined using ImageJ – Image Processing and Analysis software in Java (NIH, http://rsbweb.nih.gov/ij/index.html). Parametric analysis of variance (ANOVA) with post hoc Dunnott’s test was used to compare number of microcolonies and total covered areas between strains.

Analysis of the Transcriptomes of vicK and covR Mutants

Comparative transcriptome analyses of UA159 and mutants UAavic and UAcov were carried out using S. mutans UA159 microarrays provided by the Comprehensive Microbial Resource (CMR) of the J. Craig Venter Institute. Direct regulation of gbpB/C and gbpC/B genes by CovR and/or VicR was shown to occur at mid-log and stationary growth phase [12,14,16], therefore, cells were harvested at mid-log phase of growth in BHI (A\textsubscript{550 nm} 0.3) when expression of vicR and covR in several S. mutans strains, including UA159, is maximal [19]. Experiments were carried out using the CMR protocol M007 (revision 2.0) and M008 (revision 2.1). Briefly, cDNA was generated with random primers from 2 μg total RNA using Superscript III RT (Invitrogen), and conjugated with either Cy3 or Cy5 dyes. Slides were hybridized, washed, and scanned using a GenePix 4000B scanner (Axon Molecular Devices). Fluorescence intensities were quantified using GenePix Pro 6.0 software (Axon). The resulting files (*.gpr) were analyzed with the LIMMA algorithm interface available online at www.brop.org/idn:12496045393872 and www.brop.org/idn:12496187486126, respectively. Transcriptional activities of genes identified in the microarray analysis were confirmed by RT-qPCR.

Reverse Transcription and Quantitative PCR

Reverse transcription was carried out with 1 μg RNA using Superscript III RT (Invitrogen) as previously described [19]. Quantitative PCR was performed in an iCycler System (BioRad), and the reaction mix included template cDNA (30 ng), 30 μM of each primer, and 1× SYBR-Green mix (Biorad). The thermal cycling conditions were: 95°C for 3 min for the initial denaturation, followed by 45 cycles of three steps consisting of denaturation at 94°C for 15 s, primer annealing at 54°C for 15 s, and primer extension at 72°C for 30 s. A standard amplification curve and a melting-point product curve were obtained for each primer set. The expression levels of the genes tested were...
were purified by affinity chromatography on Ni2+...Assays were performed in triplicate with at least three independent RNA samples.

Production of Recombinant CovR, VicR, and Polyclonal Antibodies

To generate CovR- and VicR-His-Tag fusion proteins, each ORF was amplified with primers covRHisF and covRHisR or vicRHisF and vicRHisR (Table 1). PCR amplicons were restricted with NcoI and XhoI and purified products were cloned into NcoI-XhoI-digested pET-22b (Novagen) to yield pET-covR or pET-vicR. Plasmids were transformed into Escherichia coli BL21, and recombinant proteins were isolated from 1 L cultures (A550 nm 0.8) after 3 h induction with 1 mM IPTG. After cell lysis, recombinant proteins were purified by affinity chromatography on Ni2+ NTA agarose (Qiagen) and eluted r-proteins were dialyzed overnight in phosphate buffered saline (PBS) at 4°C. Aliquots of purified proteins were stored at −20°C and purity/integrity was visualized by Coomassie staining after SDS-PAGE. Polyclonal antibodies to r-CovR and r-VicR were produced using the standard 77 Days Rabbit Protocol (Covance). Antibody specificity to r-proteins was described for r-VicR, in which r-CovR showed the same binding capacity.

Cell Hydrophobicity Assays

Cell surface hydrophobicity was determined as described elsewhere [25]. Briefly, cells from BHI cultures (A550 nm 0.3) were harvested (10,000×g, 5 min), washed twice with PUM buffer (22.2 g K2HPO4•3H2O, 7.26 g KH2PO4, 1.8 g urea, 0.2 g MgSO4•7H2O per liter, pH 7.1) and resuspended in the same buffer at optical density A550 nm 0.900. Suspensions (3 ml) were mixed with 400 μl of hexadecane, by vortexing twice for 30 s, and incubated at 30°C for 30 min. Optical densities of the aqueous phases were measured at A550 nm and hydrophobicity indexes were calculated in relation to A550 nm of respective suspensions without hexadecane. Three independent experiments were performed in triplicate.

Murenoylicolytic and Autolysis Assays

The ability to cleave β-(1,4)-linkages between N-acetyl-muramic acid and N-acetyl-D-glucosamine of murein, was determined in UA159, knockout and respective complemented strains, using the EnzChek Lysozyme Assay Kit (Molecular Probes, Invitrogen). Briefly, cells were grown to mid-log phase and 50 μl aliquots of cultures were tested for lytic activity on Micrococcus lysodeikticus cell walls, which are fluorescently labeled and quenched. After 15 min incubation in the dark, 37°C, fluorescence of cleaved products was measured in a microplate reader using emission/excitation of 485/530 nm according to the manufacturer’s protocol. A standard curve generated with lysozyme chicken egg white was used to calculate activities of bacterial samples. Activities were corrected for the A550 of cultures at the time of assay and expressed relative to UA159 activity which was set to 1.0. Assays were performed in triplicate in at least three independent experiments.

The autolytic activities of strains were analyzed using a previously described assay [22]. Planktonic cells were centrifuged (10,000×g, 5 min) and washed twice with PBS. Cell pellets were re-suspended in phosphate buffer (20 mM, pH 6.5 with 1 M KCl, 1 mM CaCl2, 1 mM MgCl2 and 0.4% sodium azide) to A550 nm 0.9. Cell suspensions were incubated at 44°C and autolysis was monitored spectrophotometrically (A550 nm) at 24, 48 and 72 h. Three independent experiments were performed for each strain.

Quantification of Extracellular DNA (eDNA) in Biofilm Supernatants

The release of DNA during biofilm formation was measured in UA159, mutant and complemented strains, as described previously [26] with some modifications. Culture supernatants from 8 h biofilms were collected and harvested by centrifugation (twice at 13,000×g, 5 min, 4°C). Volumes of the cell-free samples (2 μl) were added to 1× SYBR® Green PCR Master Mix (Life Tech) containing primers for 16S RNA gene (Table S1). DNA amounts were determined by qPCR and calculated from four independent experiments and expressed relative to that from UA159 biofilms (set as 1.0).

Viability Under Osmotic and Oxidative Stress

Analysis of strain sensitivities to osmotic and oxidative stress was performed as previously described [16]. Briefly, cultures were grown to mid-log phase (A550 nm 0.3) and exposed to osmotic stress (5 M NaCl for 30 min) or to oxidative stress (10 μM H2O2 for 1 h, followed by 100 μM H2O2 for 30 min). After stress exposure, serial dilutions of cultures were plated on BHI agar to determine
the number of viable cells. Similar cultures not exposed to stress were used as control. Three independent experiments were performed in triplicate.

In silico Analysis of Promoter Sequences and Functional Classes of Genes

Promoter sequences were retrieved from the Oralgen Database, Los Alamos National Laboratories (www.oralgen.lanl.gov) and screened to identify VicR and CovR binding motifs. Promoter screening was performed using computational programs (Gibbs MotifSampler http://www.bayesweb.wadsworth.org/gibbs/gibbs.html, AlignACE http://www.atlas.med.harvard.edu and LALIGN http://www.ch.embnet.org/software/LALIGN_form.html programs). Putative functions and conserved domains of proteins encoded by genes identified in microarray screens were examined using the NCBI database (http://www.ncbi.nlm.nih.gov/gene), in information from GeneRIF (Gene Reference into Function) and relevant publications when available, were analyzed. Functional domain(s) were searched using the Non-redundant protein sequence database (RefSeq) and the Conserved Domain Database at NCBI [27].

Results

Mutations in VicK and CovR Affect Expression of Genes with Putative Roles in Cell Wall or Cell Envelope Biogenesis

Microarray-based transcriptomic comparisons between UA159 parent and vicK and covR mutant strains (UA159 and UAcov, respectively) are shown in Table S2. The fold-expression changes detected by microarray either in individual genes or in the first and last genes of potential operons were confirmed by RT-qPCR and were statistically significant (Table S2, p<0.01–0.05). Using a conservative cut off of a 3-fold expression change, a total of 23 open-reading frames (ORFs) were down-regulated and 1 was up-regulated in mutant UA159. Eleven of the down-regulated ORFs were organized into three operon-like clusters (SMU.1434c–1437c; SMU.1004–1005; SMU.1334c–1336c). Thus, a total of 15 loci were significantly down-regulated in this mutant (Table S2). Also included in Table S2 are four genes that showed changes which were slightly below the 3-fold cut-off in microarrays. These were analyzed by RT-qPCR because of previous evidence of direct regulation by VicR, e.g. gfb/C [14] or their potential functions in cell wall biogenesis (waeF and SMU.367). Previous analyses of gfb/C transcription in a UA159 vicK mutant did not reveal strong up-regulation of gfb/C, although promoter regions of these genes directly interact with VicR [14]. Thus, a 3.0 and 1.4-fold down-regulation of gfb/C observed in UA159 (Table S2), is comparable to previous observations [14].

Functional classification of gene products most significantly down-regulated in UA159 illustrates the major role of the VicRK TCS in regulating genes associated with the synthesis of and interaction with the extracellular matrix of biofilms and in cell wall biogenesis (Table S2). The most strongly down-regulated gene in UA159 was SMU.2146c, encoding a protein with a SLT transglycosylase domain (Soluble Lytic Transglycosylase) typical of lytic proteins which cleave murein linkages. This gene forms a cluster with SMU.2147c, which was designated lysM in this study, because it encodes a protein with a LysM lysozym domain typical of autolysins. Additionally, the transcription data indicate that smad, encoding an autolysin [28], is strongly repressed by VicRK (Table S2). Other genes strongly down-regulated in UA159 encode proteins involved in fatty acid biosynthesis, e.g. SMU.1334c–SMU.1336c. GbpD could also be included in this functional class of proteins, since in addition to a glucan-binding function, its participation in lipid metabolism was also established [29]. GfbB, gfbC and comC (encoding the competence peptide ComC) were also strongly down-regulated in UA159. Down-regulation of wopE in UA159 was similar to that observed for gfbC, a gene shown to be directly regulated by VicR [14]. Of note, vicR and vicX (not detected in microarray) were 1.7-fold and 2.4-fold down-regulated in UA159, respectively, as quantified by RT-qPCR. In addition, VicR down-regulation was confirmed at the protein level (data not shown).

In the UA159 covR mutant (UAcov), using a conservative cut off of 2.5-fold change, 29 ORFs were significantly up-regulated, of which 14 were organized into 4 operon-like loci. As anticipated, gfbB and gfbC were strongly up-regulated (Table S2). Given the results showing CovR binding to the gfbB promoter (below), RT-qPCR analysis of gfbB transcripts was also performed, which indicated a 1.4-fold increase in UAcov (Table S2, p<0.05). A total of 8 (27.8%) of the 29 genes up-regulated in UAcov encoded proteins with putative functions in cell wall biogenesis. These include SMU.575c (an exporter of murein hydrolases), waeF, SMU.1434c and epsC (SMU.1437c, from the operon-like locus SMU.1437c–SMU.1434c), SMU.1918c (from locus SMU.1918e–1923c), and lysM. In addition, a total of 24 ORFs were significantly down-regulated in UAcov. These included 13 genes that were also down-regulated in the mutant UA159 (SMU.1334–1335–1336–1338, SMU.1339–1341–1342–1344–1346; Table S2) and 11 not significantly affected in UAcov (Table S3).

CovR and VicR Directly Regulate Genes Involved in Cell Wall and Cell Envelope Biogenesis

EMSA assays were performed with r-CovR and r-VicR, individually and in combination, to determine whether they interact directly with the promoter regions of genes identified by transcriptome analyses as potentially regulated by both VicR and CovR (i.e. waeF, lysM, and gfbB), by VicR only (SMU.367 and smad), and by CovR only (epsC). Negative controls for r-VicR and r-CovR interactions were covR and gfbD, respectively, since we established previously that promoters of these genes were not bound by these RR. VicR binds to the promoters of the newly identified genes (SMU.367, waeF, smad1, and lysM) (Fig. 1A). CovR could bind to promoters of waeF, lysM, and epsC, and gfbB (Fig. 1B). To investigate whether r-CovR and r-VicR co-bind the promoters of genes that were regulated by each RR individually, we selected lysM, gfbB, and gfbC (shown to be regulated by VicR and CovR) [12,14], epsC (regulated only by CovR) and smad1 (regulated only by VicR). CovR and VicR could co-bind to the promoters of lysM, gfbB and gfbC leading to increased retardation of the probes compared to control genes regulated by only one regulator (Fig. 1C).

Direct regulation of gfbB by CovR was further investigated by comparing the amounts of GbpB in cell extracts and in culture supernatants of UA159, UAcov and the complemented strain. The vicK mutant (UA159) was used as a control, since GbpB production is depleted in this strain [16]. Compared to the parent, there was significantly higher production of GbpB in UAcov, which was restored to parental levels in the covR complemented strain (Fig. S1). The increase in GbpB expression in UAcov was 4-fold higher at the transcript level (cell-associated and secreted GbpB), and 1.4-fold higher at the protein level. Therefore, we compared the stability of gfbB and gfbC transcripts, by quantifying the amounts of transcript in equal amounts of RNA purified from UA159 (Ar50 = 0.3) at 0, 2.5, 5, 10, 20, 30 and 60 min after addition of rifampin to block RNA polymerase. These analyses revealed that...
Transcripts have a half-life approximately 3-times longer compared to gbpc transcripts (Fig. S1).

The VicR consensus binding motif [9] was found in the promoter regions of all other genes involved in cell wall biogenesis including SMU.367, smaA, wapE, lysM and SMU.2146c (Fig. 2). The VicR binding sequence was also reported in the promoter region of gbpB [16]. A consensus binding sequence of CovR [30] was identified in promoters of gbpB, wapE, lysM and epsC (Fig. 2), further supporting direct regulation.

Inactivation of VicRK- and/or CovR-regulated Genes does not Significantly Affect S. mutans Morphology or Cell Division during Planktonic Growth

To investigate whether the five newly identified genes of the VicRK and/or CovR regulons (lysM, SMU.2146c, wapE, smaA and epsC) function in cell wall biogenesis, knockout mutants of each gene were compared with the UA159 parent strain with regard to planktonic and biofilm growth, and cell and colony morphologies on MSA and BHI agar. Growth curves of all mutants in BHI were very similar to that of UA159 (data not shown). Additionally, SEM analysis of most mutants at mid-log (A550 nm 0.3) and stationary (A550 nm 0.9) growth phases did not reveal significant morphological changes (data not shown). The mutant in epsC (2.6-fold upregulated in UAcov and not regulated by VicRK) showed smooth colony morphology on BHI and MSA agar (data not shown), while UAcov colonies were extremely rough and adhered tightly to the agar surface. Colony morphologies of UAvic and the other four mutants did not significantly differ from UA159 (data not shown).

Because several mutants showed altered morphology during biofilm growth in the presence of sucrose (below), we examined whether sucrose would also affect morphogenesis of planktonic cells. However, addition of sucrose to culture media did not change the morphology of the mutants in the planktonic phase (data not shown).

Inactivation of VicRK- and/or CovR-regulated Genes Affects S. mutans Biofilm Growth in the Presence of Sucrose

In contrast to the observations with planktonic cells, knockout mutants smaA, SMU.2146c, lysM, and epsC clearly showed different morphologic phenotypes compared to the UA159 parent strain, when grown as biofilms on glass slides for 2 to 4 h in the presence of sucrose (Fig. S2). After 2 h of biofilm formation, mutants UAsmaA, UA2146c and UAlysM formed chains significantly longer than those of UA159, a trait most prominent in the lysM mutant. In a total of 300 chains analyzed per strain, mean numbers of cocci per chain were 11.3 (±8.1), 10.0 (±7.8), 24.8 (±13.3) in UAsmaA, UA2146c and UAlysM, respectively, which were significantly higher compared to UA159 (mean: 6.0 (±4.3) (Kruskal-Wallis, p<0.05). Mutants UAsmaA, UA2146c, UAlysM and UAEpsC were unable to form extracellular matrix-based microcolonies by 2 and 4 h, although some covered larger areas of the glass slides compared to UA159 (Fig. S2). To quantitatively analyze these phenotypes, mean numbers of microcolonies and mean covered areas of 2 h biofilms were determined using Image J software in 32 pre-determined areas per slide. As shown in Fig. 3A,
UAsmA, UA2146c, UAlysM, and UAepsC formed significantly lower numbers of microcolonies compared to parent, and smaA, UA2146c, and epsC covered significantly larger areas (Fig. 3B). Most importantly, the biofilm phenotypes were completely restored in

doi:10.1371/journal.pone.0058271.g002
all complemented mutants (Fig. S2 and 3). Mutant wapE showed no clear alteration in biofilm phenotype, although tended to form longer chains (8.61 ± 7.0) compared to UA159 (Fig. S2 and 4). The microcolony-defective phenotype of the mutants was not due to indirect effects on the genes responsible for the synthesis of and/or interaction with polysaccharides, i.e. gtfB/C/D, gbpB/C since their expression levels were not altered in the mutants compared to UA159 (data not shown).

Inactivation of VicR/CovR-regulated genes (smaA, wapE, lysM, SMU.2146c, epsC) did not significantly change the total biomass of 18 h biofilms in different media with 0.1% sucrose (data not shown), but changes in biofilm stability were noted in 8 h biofilms. Mutants in genes smaA, SMU.2146c, epsC, and, to a lesser extent lysM and wapE, formed biofilms that were loosely attached to microtiter wells, and detached during washing steps, differing from UA159 and complemented mutant biofilms (Fig. S4). Quantification of 8 h biofilms revealed significant reductions in biofilm biomass in mutants UA="sm"A, UA2146c, and UA="eps"C, compared to UA159 (Fig. 4), while reductions in biofilm biomass of UA="lys"M and UA="wap"E did not reach statistical significance (Fig. 4).

UA="vic" shows impaired biofilm formation after 18 h in BHI with 0.1% sucrose [17]. Conversely, the UA="cov" mutant shows biofilms of higher biomass compared to the parent strain after 2, 4 (not shown) and 18 h of growth (means: 1.03 ± 0.10 versus 0.50 ± 0.06 respectively; ANOVA with post hoc Dunnett’s test: p<0.01). The enhanced biofilm biomass observed in UA="cov" differs from a previous report in which a covR mutant obtained in UA159 showed reduced biomass in 48 h biofilms formed in the presence of sucrose [19].

Genes Involved in Cell Wall Biogenesis are Up-regulated during Biofilm Initiation and Sucrose Exposure

Given that the knockout mutants presented altered phenotypes associated with the initial phases of sucrose-dependent biofilm formation, we measured expression of their respective wild-type genes in the UA159 parent strain after 4 h of biofilm and planktonic growth with and without sucrose. As shown in Fig. 5, expression of covR and vicR increased approximately 1.6-2.0-fold in UA159 cells from 4 h sucrose-grown biofilms compared to those without this carbon source (ANOVA, Dunnett’s: p<0.01). In addition, gtfB/C, gbpB and the four novel VicR-regulated genes were significantly up-regulated in biofilms formed with sucrose compared to other conditions of growth. Means of 4.8 (79%), 2.2 (56%), 2.8 (64%) and 4.2-fold (76%) increases in expression of smaA, SMU.2146c, lysM and wapE, respectively, were observed in 4 h sucrose-grown biofilms, compared to biofilms grown without sucrose (ANOVA, Dunnett’s test: p<0.01) (Fig. 5). Up-regulation of the CovR-target epsC was detected in sucrose-grown biofilms to

Figure 3. Quantitative comparisons of SEM images of 2 h biofilms using Image J software. (A) Columns represent mean numbers of matrix-based microcolonies, and (B) mean coverage areas (µm²) determined in 32 pre-determined areas per strain in one representative experiment. Bars indicate standard deviations. Asterisks indicate statistically significant differences compared to parent UA159 (* p<0.05; Kruskal Wallis with post hoc Dunn’s multiple comparison). doi:10.1371/journal.pone.0058271.g003
a smaller but still significant extent, compared to other VicR targets, which might be due to increased covR expression (Fig. 5). The ghpB gene was also up-regulated in UA159 biofilms in the presence of sucrose. Expression of the VicR targets was similar between planktonic cells grown with or without sucrose, except for lysM and wapE, which were significantly more expressed in the presence of sucrose (Fig. 5). Expression of vicR, ghpB, smaA, Smu2146c and lysM in biofilms formed in the presence of sucrose was significantly higher compared to sucrose-grown planktonic cells (Fig. 5) indicating that these genes are influenced by the mode of growth as well as by presence of sucrose. However, no significant changes in transcription of most genes was observed between biofilm and planktonic cells grown in the absence of sucrose, except for gfhC and covR, which were approximately 1.6 fold down-regulated (p<0.05) in biofilms compared to planktonic cells (Fig. 5). As a control, relative expression of gyrA was analyzed which did not show significant changes in all the conditions tested.

**VicRK and/or CovR-regulated Genes Involved in Cell Biogenesis Differentially Affect Mureinolytic and Cell Surface Properties, and Stress Sensitivity**

The five novel proteins analyzed in this study have domains suggestive of functions linked to murein biogenesis or cell surface structure, which may also influence bacterial susceptibility to environmental stresses. Therefore, mutants in each gene were compared with UA159 and its vicK/covR derivatives with regard to lytic activity, cell surface properties and sensitivity to stress conditions. Inactivation of vicK and covR significantly reduced the mureinolytic activity of UA159, a phenotype completely restored in the respective complemented mutants (Fig. 6A). WapE, lysM and Smu2146c mutants also showed impaired mureinolytic activity, implying a role of these genes in cell wall biogenesis. However, mutants UA2146c and UAepsC did not show significantly altered activities compared to the parent strain. Autolysis was significantly reduced only in UAvic, UAcov, and UAwapE (Fig. 6B). In addition, epsC mutant (up-regulated in UAcov) showed a small but significant increase in autolysis at 48 and 72 h compared to UA159 (Fig. 6B). Given that lytic activities on cell walls may promote the release of DNA to the extracellular environment, we measured amounts of eDNA in the culture medium of 8 h biofilms. Mutants with impaired lytic activities, UAcov, UAwapE, and UAlysM (but not UAvic and UAsmaA) showed significantly lower amounts of eDNA compared to parent (Fig. 6C). Curiously, culture supernatants of UA2146c biofilms showed extremely high amounts of eDNA compared to UA159, and significant increases in eDNA was also observed in UAepsC (Fig. 6C). Thus, inactivation of all identified genes significantly affected mureinolytic activities and/or release of DNA to culture medium.

WapE and LysM significantly influence cell hydrophobicity, and thus might contribute to the UAvic phenotype (Fig. 6D). An increased hydrophobicity was also observed in the covR mutant, while a mutant in the CovR-target epsC did not show changes in surface hydrophobicity (Fig. 6D). None of the five novel VicR targets were involved in sensitivity to osmotic stress, except for lysM, since UAlysM was clearly resistant to osmotic stress (Fig. S4). Because lysM is down-regulated in UAvic, other yet unknown genes are likely involved in the sensitivity of this strain to osmotic stress. As previously observed [14], vicK inactivation did not significantly affect UA159 sensitivity to H2O2. However, wapE, a VicR-target, was significantly involved in resistance to oxidative stress (Kruskal-Wallis, p<0.01; Fig. S4). In summary, some of the new VicR/CovR target genes are involved in cell surface properties and sensitivity to osmotic and oxidative stress.

**Discussion**

The roles of the TCS VicRK and CovRS have been investigated in several species of *Firmicutes*, including the major streptococcal pathogens *S. pneumoniae*, *S. pyogenes*, and *S. agalactiae* [31–34]. Both TCS regulate biogenesis of the cell surface in a species-specific manner [9,32,35–37], likely as result of evolutionary adaptation to the respective host/environmental niches. Changes in transcriptomic profiles of vicK and covR mutants are significantly influenced by nutritional and growth conditions [37–39], which may explain why some genes affected in this study of UAvic, e.g. wapE, and UAcov, e.g. SMU.2146c, were not detected in previous transcriptomic analysis of similar mutants of *S. mutans* [37–40]. SMU.2146c/2147c and SMU.367 were detected in microarray analysis of a vicK mutant obtained in UA159 grown at pH 5.5, but the biological function of these genes was not
Figure 5. RT-qPCR analysis of gene expression in strain UA159 in 4 h biofilms and in planktonic phase. Biofilm (B) and planktonic (P) cells derived from the same cultures were grown in medium with or without 0.1% sucrose as indicated. Levels of transcripts in cells from sucrose-grown biofilms were set to 100% in order to calculate relative amounts of transcripts from cells grown under other conditions (biofilms w/o sucrose and planktonic cells). Columns represent means of three independent experiments performed in duplicate. Bars represent standard deviations. Statistically significant differences in gene expression in biofilm or planktonic cells grown without sucrose compared to the respective sucrose-grown cells are indicated above columns of cells without sucrose. Differences between biofilm and planktonic cells grown in the presence of sucrose are indicated above brackets. Statistical comparisons between biofilm versus planktonic cells in absence of sucrose are not shown. ANOVA with post hoc Dunnett’s test: * p<0.01, § p<0.05.

doi:10.1371/journal.pone.0058271.g006
examined [38]. In *Bacillus subtilis* and in *S. pneumoniae*, VicK (YycG) is localized in the divisome and coordinates synthesis of autolysins and autolysin inhibitors during growth via kinase activation of VicR (YycF) [10]. In *S. mutans*, inactivation of vicK affects septum division, cell wall properties, biofilm formation and bacteriocin production [14,16,39] warranting an in-depth examination of gene functions associated with these phenotypes.

In the present study, we provide data that supports a model in which VicRK and CovR regulate several genes involved in cell wall biogenesis to optimize bacterial surface interactions with the extracellular matrix during sucrose-dependent biofilm growth in *S. mutans*. Defective biofilm phenotypes at 2, 4 and 8 h of growth were detected in mutants smaA, SMU.2146c, lysM, and epsC included impaired formation of microcolonies and/or biofilm fragility (Fig. 4, S2, S3), implying a significant influence of each gene in biofilm formation. An exception was wapE, whose inactivation promoted only a minor change in biofilm phenotypes (Fig. 4, S3), as described previously [41]. This observation may result from the static conditions under which biofilms were grown in *vitro* with high levels of glucan favoring increased biomass. Similarly, defects in microcolony formation or fragility detected in 2 to 4 h biofilms of UAlysM (Fig. S3) did not reflect significant changes in total biomass of 8 h biofilms (Fig. 4). Thus, analyses of mutants in multiple genes are needed to determine the contribution of lysM and wapE to biofilm formation.

Defining the specific functions of genes involved in cell wall biogenesis is important in order to clarify the transition from planktonic to biofilm growth in *S. mutans* in the presence of sucrose. Among the VicR-regulated genes (smaA, lysM, wapE, SMU.2146c), smaA showed mureinolytic activity, consistent with previous reports [31], as well as lysM and wapE (Fig. 6). LysM encodes a protein with a LysM domain, which is common in autolysins and likely involved in presentation of murein target sites for cleavage, e.g. cell wall septum [42]. Although no known mureinolytic domain is present in WapE, the protein has a N-terminal YSIRKR lipoprotein signal motif which targets proteins to the septum in dividing Gram-positive bacteria [43] and thus WapE may coordinate cell division with cell surface biogenesis. SMU.2146c encodes a protein with an SLT transglycosylase domain known to degrade murein via cleavage of the β-1,4-glycosidic bonds of murein. Mutation in this gene did not impair mureinolytic activity or autolysis, but promoted release of large amounts of DNA during biofilm growth (Fig. 6), suggesting cell wall defects which may also be related to the long chain phenotype of UA2146c in biofilms (Fig. S2). Although DNA release reflects bacterial lysis [44], it can also occur in the absence of detectable autolysis in streptococcal species found in dental biofilms [45]. Interestingly, although changes in morphogenesis were evident in initial biofilms of mutants UAsmaA, UA2146c, UAlysM and UAepsC, (Fig. S2), these changes were weak or absent during planktonic growth in all mutants tested, indicating that there are cell biogenesis pathways specific to biofilm growth in *S. mutans*.

The associations between defects in biofilm initiation and fragility of 8 h biofilms were most noticeable in the presence of sucrose (Fig. 4), indicating defective interactions of cells with glucan or abnormal synthesis of glucan on the cell surface. Thus, the biofilm defective phenotype of the vicK mutant may result from accumulated changes in several protein functions, in addition to abnormal extracellular synthesis of polysaccharides by GtfB/C and Ftf [14] and cell-matrix interactions mediated by GbpB [16]. The up-regulation of gfbB/C during biofilm growth and in response to sucrose have been reported in several studies [46,47]. In this study, we show that gfbB, smaA, lysM, SMU.2146c and wapE are also significantly up-regulated during the initial steps of biofilm formation (Fig. 5). Transcriptome studies of *S. mutans* biofilms formed on different surfaces, also detected up-regulation of *SmaA* and SMU.574c (adjacent to murein hydrolase exporter SMU.575c) identified in this study; Table S2 [40] and wapE [41]. It is noteworthy that wapE and lysM are up-regulated even in planktonic cell populations exposed to sucrose compared to cells grown without sucrose (Fig. 5).

Sucrose is the only substrate for glucan synthesis by GtfB/C, and, to our knowledge, this is the first study showing that in *S. mutans* cell wall biogenesis genes coordinate sucrose-dependent biofilm formation under the direct control of VicRK and CovR. The VicK sensor kinase may auto-phosphorylate in response to as yet unknown environmental signals generated during biofilm growth and/or bacterial interaction with newly synthesized polysaccharides. Although amounts of VicR were not quantified, in UA159, vicR is up-regulated during initial biofilm growth in the presence of sucrose (Fig. 5), a finding also reported for strain GS5 [48]. Although vicR and vicA were down-regulated in UAvic, vicR self-regulation was not investigated in this study, and was not reported in other Gram-positive bacteria [49,50]. We assume that in wild-type cells VicR is activated by phosphotransfer from VicK, however, other TCS may also play a role in *vicR* expression, e.g. LiaFSR and ComCDE TCS [51,52]. Data from this study suggest that growth of *S. mutans* in biofilms involves dynamic cooperation between VicR and CovR, since CovR directly represses several genes of the *vicR* regulon, as well as gbpC and epsC, all involved in cell surface biogenesis and biofilm structuring (Table S2, Fig. 1/2; [18,37]). Despite the direct interaction of r-CovR with the gbpB promoter (Fig. 1), increase in gbpB transcription in UAcov was relatively low (1.4-fold; p<0.05), compared to other CovR targets, e.g. gbpC (4.6-fold up-regulated) (Table S2). However, a greater increase in GbpB protein (4-fold) was found in UAcov compared to its transcript (Fig. S1), which might be explained by differences in transcript stabilities of CovR regulated genes. For example, gpbC up-regulation was approximately 2.2-fold in the covR mutant IBS132 [23] and 4.6-fold in UAcov (Table S2) although the half-life of these transcripts is very short (less than 2-8 min) in UA159 ([23], Fig. S1). Transcriptomic profiles of UA159 covR mutants revealed that CovR acts both as a negative and a positive regulator ([37], Tables S2 and S3). Genes wapE and gfbD were significantly up-regulated in *covR* mutants obtained in strains UA159 (IBS10) and UA130 (GMS900), although direct binding of CovR to the respective promoters was not investigated [18]. We show that CovR directly represses the CovR-targets (wapE and lysM), but not gfbD (Table S2, Fig. 1 and 2). EspC was also directly repressed by CovR (Table S2; Fig. 1, 2), and since it is up-regulated during biofilm growth in the presence of sucrose (Fig. 5), this gene may also be controlled by other transcriptional factors. In Gram-positive bacteria, epsC encodes a UDP-N-acetylgalactosamine (GlcNAc) 2-epimerase which catalyzes the reversible interconversion of UDP-GlcNAc and UDP-N-acetylmannosamine (UDP-ManNAc). The latter is required for attachment of teichoic acids to the cell wall, and for the biosynthesis of cell surface polysaccharides [53]. The lytic activity of the epsC mutant was similar to that of UA159, but there was a significant increase in DNA release (Fig. 6), possibly due to increased cell wall permeability during biofilm growth. The UApC mutant showed significant defects in biofilm formation at 2, 4 and 8 h of growth (Fig. 3, S4, S2, S3), indicating a role of EpsC in sucrose-dependent biofilm formation.

VicR and CovR are members of the OmpR family, and as such contain a single winged helix structure for DNA binding [49,54]. However, while VicR binds to a conserved DNA motif [49], which was found in all genes identified in this study (Fig. 2), a consensus
target sequence for CovR was not discovered. In GAS, CovR binding depends on the structure assumed by CovR dimers formed after phosphorylation [54,55] and the affinity of CovR-promoter interactions frequently involves phosphorylation-induced oligomerization to cover AT-rich DNA sequences [30,54]. However, phosphorylation or cooperativity does not always affect CovR binding [54,55]. A search for AT-rich consensus sequences in the promoters of the CovR-target genes identified in this study revealed several putative binding motifs (Fig. 2). In addition, EMSA assays show that VicR and CovR are able to co-bind the promoter regions of several genes (Fig. 1C).

In summary, the present study identified and characterized a set of new CovR and VicR targets involved in *Streptococcus* cell wall/surface biogenesis, which are implicated in sucrose-dependent biofilm growth and structure. Further, we present evidence that CovR and VicR may interact cooperatively to coordinate functions of several genes, opening a new line of investigation to decipher roles for these important systems in the physiological transition from planktonic to biofilm growth of *Streptococcus*.

Supporting Information

**Figure S1** Effects of *cooR* inactivation on GbpB production, and gbpB transcript stability. (A) Relative amounts of GbpB in cell extracts (0.5 μg) and culture supernatants (2.5 μg) of mid-log phase cultures (*A<sub>550 nm</sub>* 0.3) were determined by densitometry of western blots of GbpB probed with anti-GbpB antibody. Columns represent mean amounts of GbpB produced by *cooR* mutant (UAcooR) and its complemented mutant (UAcooR*) compared to UA159 (set to 1). Results were calculated from three independent experiments. Bars represent standard deviations. Asterisks indicate significant differences compared to UA159 (*p* < 0.01) tested by ANOVA with *post hoc* Dunnett’s test (A) or by Kruskal-Wallis (B).

**Figure S2** Biofilm phenotypes after 2 and 4 h of growth in the presence of sucrose. Mutants of VicR and/or CovR-regulated genes are indicated below the respective panels. Complemented mutants are indicated by “+”. Biofilms of parent strain UA159 are shown in the two panels at bottom.

**Figure S3** Biofilms formed during 8 h in the presence of sucrose. Mutants of VicR/CovR-regulated genes (indicated above the respective panels) showed abnormal structure and detachment during washing steps of biofilms (arrows). These properties were not observed in parent UA159 or complemented mutants (indicated by “+”).
