Abstract

Background: Identifying the arterial variation of the lateral circumflex femoral artery is a vital step in planning surgical and radiological approach. To evaluate the variations and discuss the clinical correlates of the lateral circumflex femoral artery.

Materials and methods: 58 adult cadavers (male 45, female 13) with 115 usable sides were used to assess and classify the origin and branches of the lateral circumflex femoral artery. Also its external diameter, distance from mid-inguinal ligament to sites of origin from the profunda femoris artery or femoral arteries.

Results: There were 7 types of lateral circumflex femoral artery variations in this sample. We classified them as types A to G, of which type A was normal, that is, the one showing a single lateral circumflex femoral artery arising from the profunda femoris artery. Nearly 50.43% of the sample had type B-G variations, each having 13, 10, 23, 4, 4 and 3 cases, accounting
for 11.30%, 8.70%, 20.00%, 3.48%, 3.48% and 2.61%, respectively.

**Conclusions:** There are many variant types in the lateral circumflex femoral artery. To avoid iatrogenic injuries, clinicians must have a sound understanding of the variation types of this important blood vessel.

**Key words:** lateral circumflex femoral artery, variation, anatomy, clinical significance

**INTRODUCTION**

The lateral circumflex femoral artery (LCFA) branches from the lateral part of the root of the profunda femoris artery (PFA) and runs horizontally and laterally on the back of the sartorius and rectus femoris muscles. It divides into ascending, transverse, and descending branches (1). There are several reports of variations of the LCFA and PFA (2-4) including many case reports in domestic and international literature. Statistically, there is a dearth of published literature analyzing the morphometric, types of variations, and clinical significance of the LCFA. With the continued development of vascularized skin flap and vascularized bone reconstruction transplantations as well as the improvement in radiological diagnosis and treatment of peripheral vascular diseases, PFA and its branches have become of important clinical value (5). In particular, the LCFA and its branches are of great significance in the vascular transplantation and restruction surgery (6-8). Therefore, this study was designed to provide detailed anatomical data for clinical use by analyzing the variations of the LCFA in a sample of 58 cadavers.

**MATERIALS AND METHODS**

**Materials**

Fifty-eight (male 45, female 13) formalin-fixed adult cadavers from the Department of Human Anatomy, Sun Yat-sen School of Medicine were used in this study resulting in 115 usable lateral circumflex femoral arteries. Dissection instruments for routine use in gross anatomy such as scalpels, hemostatic forceps, etc.
were used. A calibrated Vernier calipers was used for measurement (accuracy 0.01 mm). The specimens were preserved in 10% neutral formalin fixative solution.

**Methods**

The formalin-fixed and undissected cadavers destined to be used in gross anatomy teaching/dissections (i.e. the skin of the lower abdomen and upper thigh did not have any surgical marks or signs of having been dissected) were selected for meticulous exposure of the femoral artery, its profunda branch as well as the LCFA. The origin of FA and LCFA and their branches were carefully exposed and observed following a pre-established protocol of lower limb femoral region dissection described previously (9). Verification of the identities, courses, and branches of the FA, PFA, and LCFA, as well as any variations, were done by two senior anatomists (XDZ and JMH, corresponding authors). The external diameters of the FA, PFA and LCFA, the distance between the starting point of the PFA and the midpoint of the inguinal ligament, and the distance between the starting point of the LCFA and the starting point of the PFA were measured with a Vernier caliper and string tracing method. The (Z3i, vivo, China) smartphone was used for recording the images of the in situ anatomy and any variations encountered.

**RESULTS**

Our team conducted an anatomical study on 115 extremities of 58 cadavers. There were 7 types of origin variations of the LCFA, namely type A (one single LCFA originated from the PFA, Figure 1); type B (one single LCFA originated from the FA, Figure 2); type C (one single LCFA and PFA that arose from a common stem, Figure 3); type D (two LCFAs both originated from the PFA, Figure 4); type E (one LCFA originated from the PFA, while the other originated from the FA, Figure 5); type F (one LCFA originated from the PFA, the other arose from a common stem with the PFA, Figure 6); type G (one LCFA originated from the FA, the other arose from a common stem with the PFA, Figure 7).

Type A was the most prevalent variation (58 out of 115, 50.43%) while 13 out of
the 115 specimens (11.30%) were type B. The average distances from the midpoint of
the inguinal ligament to the origins of the LCFA and the PFA from the FA were 42.65
(±13.87) mm and 33.15 (±16.37) mm, respectively. The average external diameter of
the FA was 9.50 (±2.53) mm while that of the PFA and the LCFA were 4.79 (±1.26)
mm and 4.37 (±1.13) mm, respectively (Tables 1 and 2).

Ten out of 115 (8.70%) femoral region specimens had type C variation of the LCFA
origin. The average distance between the midpoint of the inguinal ligament and the
common origin of the PFA and the LCFA from the FA was 34.23 (±9.96) mm. The
average external diameter of the FA was 9.50 (±2.53) mm while that of the PFA and
the LCFA were 4.79 (±1.26) mm and 4.37 (±1.13) mm, respectively (Tables 3 and 4).

Twenty-three out of 115 (20.00%) specimens bearing the origin of the LFCA were
of type D. In this type, the proximal LCFA was defined as LCFA-a, while the distal
one defined as LCFA-b. The average distances from the inguinal ligament midpoint
to the origin of the LCFA-a and the LCFA-b from the PFA were 17.26 (±13.26) mm and
30.22 (±13.84) mm, respectively. The average distance from the midpoint of the
inguinal ligament to the exit point of the PFA from the FA was 42.51 (±14.55) mm.
The average external diameters were as follows: the FA was 8.44 (±2.41) mm, that of
the PFA was 5.91 (±1.89) mm, the LCFA-a was 3.77 (±1.10) and the LCFA-b was
3.17 (±1.16) mm (Tables 5 and 6).

Four out of 115 (3.48%) specimens were variation type E. In this type, the LCFA
that originated from the FA was designated LCFA-a, while the one coming from the
PFA was designated LCFA-b. The average distances from the midpoint of the inguinal
ligament to the origins of the PFA and the LCFA-a from the FA were 46.84 (±4.09)
mm and 47.25 (±26.48) mm, respectively. The LCFA-b sprung from the PFA about
18.55 (±7.03) from where the PFA exited the FA. The average external diameters of
the arteries were as follows: the FA 9.14 (±2.65) mm, the PFA was 5.54 (±1.36) mm,
LCFA-a 3.16 (±1.28), and the LCFA-b was 4.23 (±1.28) mm wide (Tables 7 and 8).

The type F variations were also encountered in 4 of the 115 (3.48%) specimens. In
this variation type, the LCFA and the PFA shared a common origin defined as LCFA-
a, while the other one independently arose from the PFA and was named the LCFA-b.
The mean length of the LCFA-a from the midpoint of the inguinal ligament to its FA origin was 49.64 (±12.40) mm. The LCFA-b exited the PFA about 25.26 (±6.64) mm down the course of the PFA. The average external diameters of the arteries as follows: FA 10.24 (±0.78) mm, PFA 6.20 (±0.77) mm, LCFA-a 4.48 (±1.91), and LCFA b 3.04 (±1.43) mm (Tables 9 and 10).

Only 3 out of 115 specimens (2.61%) were type G variations. In this type, the LCFA arising from a common origin with PFA was defined as LCFA-a, while the one arising directly from the FA named LCFA-b. The average distance from the midpoint of the inguinal ligament to the common origin of the PFA and the LCFA-a from the FA was 92.92 (±4.40) mm. The average distance from the midpoint of the inguinal ligament to the origin of LCFA-b on the FA was 45.72 (±6.18) mm. The average external diameters of the arteries were as follows: FA-9.85 (±0.73) mm, PFA-6.04 (±0.54) mm, LCFA-a-3.61 (±1.11), and LCFA-b-5.11 (±0.76) mm (Tables 11 and 12).

**Figure 1.** Showing Type A variation in which one single LCFA originated from the PFA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery (LCFA).
Figure 2. Showing Type B variation in which one single LCFA originated from the FA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery (LCFA).

Figure 3. Showing Type C variation in which one single LCFA and PFA that arose from a common stem. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery (LCFA).
**Figure 4.** Showing Type D variation in which two LCFA's both originated from the PFA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: the proximal lateral circumflex femoral artery (LCFA-a), 4: the distal lateral circumflex femoral artery (LCFA-b).

**Figure 5.** Showing Type E variation in which one LCFA originated from the PFA, while the other originated from the FA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery originates from FA (LCFA-a), 4: lateral circumflex femoral artery originates from PFA (LCFA-b).
Figure 6. Showing Type F variation in which one LCFA originated from the PFA, the other arose from a common stem with the PFA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery arises from the common origin with PFA (LCFA-a), 4: lateral circumflex femoral artery originates from PFA (LCFA-b).

Figure 7. Showing Type G variation in which one LCFA originated from the FA, the other arose from a common stem with the PFA. A picture: 1: femoral artery (FA), 2: profunda femoris artery (PFA), 3: lateral circumflex femoral artery arises
from a common origin with PFA (LCFA-a), 4: lateral circumflex femoral artery originates from FA (LCFA-b).

DISCUSSION

The profunda artery and the lateral femoral circumflex artery are prone to having many types of variations. Previously, Shi and colleagues described the variations of the lateral circumflex femoral artery and divided them into four categories namely those originating from the profunda femoris artery and those from the femoral artery as well as the number of roots of origin (10) accounting for 25.00% and 76.56%; 90.62% and 9.38%, respectively. If classified according to this method, the four types of data measured by the author account for 15.15% and 84.84%; 70.43%, and 29.57%, respectively. The frequency with which the lateral circumflex femoral artery emanated from the profunda femoris artery was higher than that from the femoral artery, and the number of cases with a single femoral circumflex artery was also more than those with a double. These findings were consistent with the results of Shi et al (10). The majority of the lateral circumflex femoral arteries originated from the profunda femoris artery while a fewer were from the femoral artery or the common stem with the profunda femoris artery (11). Daksha Dixit et al. (12) studied 114 cases (228 specimens) and found that the lateral circumflex femoral artery originated from the profunda femoris artery in 171 specimens (75%), from the femoral artery in 18 specimens (7.89%) and also from a common stem in 31 specimens (13.59%). Labetowicz et al. (9) found that the lateral circumflex femoral artery arises from the profunda femoris artery or the femoral artery in 78.75% and 21.25% of cases, respectively. Also, Tomaszewski et al. (13) reported that the lateral circumflex artery was a branch of the profunda femoris artery and the femoral artery in 76.1% and
19.6%, respectively. Liu et al. (5) divided branches of the profunda artery into four types based on clinical application. In the present sample of 115 cases, the lateral femoral circumflex arteries were classified according to their origin and number of roots giving rise to 7 types (6 of which were variations). The prevalence of the variations, named herein type A to G, was 50.43%, 11.30%, 8.70%, 20.00%, 3.48%, 3.48% and 2.61%, respectively.

Based on the variation type, the distance from the mid-point of the inguinal ligament to the origin of the profunda femoris artery was 40.41±13.72 mm (minimum 13.73 mm, maximum 83.64 mm). Nasr et al found that the mean distance between the midpoint of the inguinal ligament and the origin of PFA and was 51.5±1.9 mm on the right side and 49.7±1.9 mm on the left side in males, and 48.5±2.2 mm on the right side and 48.9±2.2 mm on the left side in females (14). This difference in morphometric data could be the result of individual and racial differences in anthropometric characteristics. Interventions involving cannulation of the femoral artery are being widely used in clinical practice (12). During the process of puncturing the femoral artery and inserting a cannula, the profunda femoris artery should be avoided as much as possible to prevent the guidewire and catheter straying into it. If the profunda femoris artery is abnormally placed or the origin too high, the guidewire and catheter might easily stray into it (15). This study provides anatomical data that can help access the femoral artery during clinical intubation, and doctors should pay attention to the unique situation of each patient during femoral artery puncture.

According to the variation type, the diameter of the lateral circumflex femoral artery was 4.30±1.43 mm (minimum 1.01 mm- maximum 7.91 mm) and the average point of origin of the lateral circumflex femoral artery was 56.98 mm below the inguinal ligament. The deep branch (ascending branch) of the lateral circumflex femoral artery nourishes the femoral head and neck, and the diameter and position of the vessel should allow for catheter insertion. This feat can easy and safe to treat avascular necrosis of the femoral head (16). Therefore, data contained in this article provide an anatomical basis for safe endovascular interventions in the treatment of avascular necrosis of the femoral head via the ascending branch of the lateral
circumflex femoral artery.

The applied anatomy of the lateral femoral circumflex artery, an important branch of the profunda femoris artery, is of great significance in the clinical. For instance, it is responsible for vascularization of the greater trochanter, head, and neck of the femur as well as the vastus lateralis muscle and the knee complex (13). The lateral femoral circumflex artery (LFCA) is closely associated with the soft tissues around the hip joint and the head and neck of the femur, putting it at risk during traumatic damage to the hip joint and femoral neck (17, 18). Knowledge of the anatomical variations of the profunda femoris artery and its circumflex branches is vital in angiographic diagnostic procedures and during surgical or radiological interventions involving the femoral region. Orthopedic surgeons and interventional radiologists must be aware of potential variations of the site of origin and course of the LFCA when performing clinical operations such as femoral triangle surgery and hip joint replacement, and vascular radiological intervention such as arterial catheterization and arteriography (19, 20), as a means to avoid iatrogenic injury and decrease the risks of intra-operative posthemorrhage, as well as post-operative complications. For instance, the popular anterior approach of hip surgery routinely requires the ligation of the ascending branch of the LCFA. It may jeopardize vascularization of the proximal femur, especially in conditions of anatomical variations (21).

It is also widely used and of surgical value in thigh flaps (22). The thigh flap supplied by LCFA and its branches has a great clinical significance in flap plastic surgery, including repairing large soft tissue defect of the extremities (23), head-and-neck region (24) and knee (25), as well as reconstructing defects resulted from perineal and hypogastric tumor resection (26). For example, the retrograde anterolateral femoral flap with a descending lateral branch of the femoral circumflex artery and the perforating branch of the lateral superior genu artery can better repair soft tissue defects around the knee and middle and upper leg, with sufficient blood supply and satisfactory outcomes (27). Nevertheless, the anatomical variability of the LCFA complicate the harvest of thigh flaps, thus adequate awareness of these anatomical properties will be conducive to flap refinements and donor-site
management (28).

The expanding scope of vascular transplantation and reconstruction has prompted this study on the variations of LCFA and its branches. Besides, in patients with iliofemoral artery thrombosis, the lateral circumflex femoral artery can provide an alternative outflow route for the main artery bypass (6). Besides, it can be utilized as a high-flow conduit in extracranial–intracranial (EC–IC) bypass surgery in patients with intracranial disease requiring sacrifice of the parent vessel, for example, aneurysm (8). In recent era, the descending branch of the lateral circumflex femoral artery has gained popularity in coronary artery bypass grafting. It is worth noting that related clinical trial group encountered an 18 to 20% abandonment rate secondary to anatomical factors (7).

In order to prevent iatrogenic injury and minimize complications, it is of vital importance for radiologists and surgeons to take the variations of LCFA into account during operations in the femoral region and diagnostic interventional procedures, as well as in the field of vascular, plastic and reconstructive surgery. Therefore, a careful examination of blood vessels should be emphasized prior to performing any invasive procedure in femoral region.

CONCLUSIONS

The data of this study provided anatomical variations of the lateral circumflex femoral artery and recommend that doctors should have a sound understanding of its variations along with those of the profunda artery. This important to prevent iatrogenic injuries and improve clinical outcomes.
