We propose a model of network growth in which the network is co-evolving together with the dynamics of a quantum mechanical system, namely a quantum walk taking place over the network. The model naturally generalizes the Barabási-Albert model of preferential attachment and it has a rich set of tunable parameters, such as the initial conditions of the dynamics or the interaction of the system with its environment. We show that the model produces networks with two-modal power-law degree distributions, super-hubs, finite clustering coefficient, small-world behaviour and non-trivial degree-degree correlations.

PACS numbers: 89.75.Hc, 03.67.-a, 89.75.-k

Models of graph growth are important for studying and simulating the behaviour of a large variety of real-world phenomena and for the in silico construction of networks with given properties. Growth processes occur ubiquitously in social systems, technology, and nature. See, for example, Ref. [1] for overviews on complex networks growth. Among the most extensively studied models of network growth are those based on preferential attachment – or “the rich get richer” scheme – together with its many variations [4]. Predating networks science, the basic idea behind preferential attachment goes back to the 1920s and the work of the statistician Yule [5]. The set-up usually consists of two ingredients: an iterative process in which new nodes are sequentially added to an existing graph; and a mechanism for choosing the neighbours of newly arrived nodes. Only when the preference on the neighbours is a linear function of the degrees of the nodes, then the degree distribution of the growing graph turns out to be a power-law, as those observed in the majority of real-world complex networks. The literature contains many variants of preferential attachment, respectively defined by local rules, fitness, redirection, copying, substructures, games, geometry, etc. [6].

We are interested in generalizing the classical preferential attachment model, in which the choice of the nodes to link to is specified by the dynamics of random walks [7]. The original idea, illustrated in Refs. [8][10] is simple. Imagine a walker moving along the edges of a graph. At a given node, the walker chooses to stay where it is or to move to one of the neighbouring nodes with a fixed but arbitrary probability. If we wait long enough, the probability that the walker is at a specific node is proportional to the number of its neighbours: this probability converges towards a unique stationary distribution and is independent of the starting node – a fundamental property in algorithmic applications of Markov chains [11][12]. Once we are close enough to the stationary distribution, we add a new node to the graph, and choose its neighbours according to the occupation probability distribution induced by the walker. If we keep adding nodes in this way, we eventually grow a graph whose degree distribution follows a power-law. When the walker makes an unbiased choice at each node, i.e. when the stationary occupation probability of the walker at node i is a linear function of the degree of i, then this mechanism produces exactly the Barabási-Albert (BA) random graph [5], which is the most widely studied outcome of preferential attachment so far.

Graph growth indeed fits into a larger picture, namely the study of dynamical graphs, i.e., graphs changing in time. This is a direction that is currently generating interest as a natural development of static network theory (see Ref. [12] is a recent review). Letting the structure of a graph co-evolve together with a dynamical process is a particularly appealing and well-motivated idea. In particular, the existence or activity of a node and the strength of a link can be time-dependent on the state of a dynamical process taking place on the graph. For instance, if the nodes of a graph represent individuals having an opinion which changes over time according to a certain rule, and the links stand for friendship among nodes, then the existence and strength of each link can change over time as a function of the difference of opinion between adjacent nodes. People usually tend to remain
linked with neighbours who share similar opinions, and to sever links to other individuals having different opinions. In this case the structure of the network depends on the distribution of opinions and, on the other hand, the opinion dynamics depends on the actual connection pattern. In a single word, the network and the opinion formation process are co-evolving. Opinion formation is of course only a very specific example of a process able to drive the evolution of a network. Many other models of networks co-evolving with synchronization [14], diffusion [15], and voter models [16, 17] have been discussed in the last decade (see also Ref. [18]).

Networks seen as states of a quantum mechanical system co-evolving together with a classical process have been proposed to explore the role of emergence in approaches to discrete quantum gravity [19]. Networks whose edges correspond to bipartite states – essentially certain circuits with two-qubit gates – have been studied in relation to entanglement distribution [20].

With the aim of designing a new methodology to grow complex networks, we ask the following question: what happens when we consider a graph whose growth depends on the state of a quantum mechanical system? In particular, we are interested in replacing the random walk dynamics, which produces the BA random graph, with a quantum dynamics. At each step of the growth process, the neighbours of the newly added node are chosen by observing the state of the quantum system – by using a standard (von Neumann) measurement. We have the co-evolution of two processes: each step of the graph growing process depends on a quantum dynamics and, conversely, the dynamics takes place in a phase space (the graph) modified during the growth.

Quantum walks have been extensively studied in the last forty years: a continuous version is discussed in [21] and dates back to 1964; a discrete version was introduced in the 1990’s [22]. During the past decade, quantum walks have acquired an important role in the context of quantum computation as a methodology for designing algorithms [23, 24]. Quantum walks are also essential in modeling quantum buses for the transfer of information in nanodevices. The dynamics of an exciton in a spin chain or an arbitrarily coupled spin system is modeled by a coherent quantum walk [25, 26]. Additionally, the transport of energy in large molecular complexes has been explained using a class of quantum walks whose evolution is assisted by interactions of the system with a noisy environment [27]. Very recently, quantum walks have also been employed for the characterisation of complex networks [28, 29].

The quantum walker, like the classical (i.e., random) one, induces a probability distribution on the nodes of a graph. However, the distribution is obtained by measuring the state of the system at a given time in quantum mechanics, the state (of a closed system) is identified with a unit vector in a complex phase space, with probabilities substituted by amplitudes. A major property of quantum walks is the existence of interference effects during the dynamics. Once the position of the quantum walker is measured, the corresponding probability distribution is the result of an interference pattern. Notably the distribution does not converge in time because the evolution of a quantum mechanical system is completely reversible [22, 30]. The dynamics can be periodic, or quasi-periodic, but there is no convergence unless we take a time-average – or we stop the evolution at a given time. Interference is one of the ingredients that permits algorithms of good performance to be designed [32] and is responsible of many counterintuitive behaviours of quantum systems. For instance, transporting a packet of information from one node to another node without error, even if routed “randomly” through the graph – a phenomenon called perfect state transfer [37]; or reaching far away nodes with an average probability that is exponentially higher than that for the classical analogue [38]. It is also remarkable that quantum walks have been successfully implemented through various experimental schemes involving light or matter [34, 36].

Here we work with continuous-time quantum walks (CTQW). In these processes the matrix defining network links is interpreted as the system Hamiltonian: this is the operator corresponding to the total energy of the system. The Hamiltonian specifies the interactions between the particles associated with the nodes in terms of coupling strengths. CTQWs are reversible by definition, since the dynamics is governed by the Schrödinger equation. (A formal definition is given in Appendix.)

What can we say about graphs whose growth depends on the state of quantum walks? Do they have structural properties comparable to those of the BA random graph? The time at which the measurement is performed (i.e. the time at which the walk is stopped) drastically influences the distribution of attachment probabilities; moreover, the choice of the node from which the walk is started may affect the occupation probability distribution measured at a certain time. These facts reflect the much richer behaviour of quantum walks with respect to random walks. In order to associate a probability distribution to the CTQW, we consider the time-average of all distributions obtained by running the walk for a given time. At each step of the iteration, we could choose the distribution obtained by stopping the walk at a time determined by a function of the number of nodes. We choose here (arbitrarily) to run the walk for an infinite time – this is like stopping the walk at a random time and it looks like a good choice for exploring the general idea. The time length of each walk is in fact a tunable parameter, differently from the classical BA model in which the growth depends on the long-time dynamics of the walk.

We consider here three alternatives for the starting node used to seed the quantum walk: a) the walks always start from the initial node, i.e. the node added at the first step of the graph growing iteration; b) the walks always start from the node added at the last step; c) at each step, the starting node is chosen at random – of course, we could consider any probability distribution.
FIG. 1. The structural properties of the final network heavily depend on the choice of the starting node for the quantum walks. If the walks start from the node used to seed the growth process (upper left panel), we get a two-mode power-law degree distribution. In this case there is a non-negligible probability of forming a super-hub which condenses a large fraction of the edges of the network. Also, the final network has pronounced disassortative degree-degree correlations (lower left panel). Conversely, if the walk starts from the lastly added node, or from a randomly selected one, then the degree distribution of the final network is instead exponential (upper right panel). In this case there are slightly assortative degree-degree correlations (lower right panel). The results are based on 20 realizations with \( N = 3000 \) nodes and \( K = 9000 \) edges for each scenario.

on the set of existing nodes. Since the growth is driven by the quantum walk which effectively acts as a “controller”, we expect different asymptotic distributions. On the one hand, obtaining the time-average of a CTQW is a tractable problem; but on the other hand, predicting the properties of our growing graphs is a difficult one because the time-average has erratic behaviour [38]. Presenting an analytic treatments of the asymptotics remains an open problem.

In Fig. 1 we report the results of numerical simulations of the model with different initial conditions. We have constructed networks with \( N = 3000 \) nodes and \( K = 9000 \) links. We observe that different choices of the starting node produce graphs with different structural properties. For selection \((a)\), the final graph is characterized by a two-mode power-law degree distribution (upper left panel) and has super-hubs, i.e. nodes with degree of the same order of the total number of nodes. Such exceptionally highly-connected nodes are usually among the oldest ones, i.e. the nodes added in the very first steps of the iteration. Each super-hub turns out to be incident with up to 30% of the total number of edges in the final graph. This condensation phenomenon is indeed observed in real communication and information networks, including the Internet and the World Wide Web, and in biological networks [3]. Notice that the degree distribution obtained in \((a)\) is different from that obtained for the BA random graph shown in the same panel. An obvious by-product of the existence of a super-hub is that the average length of the shortest paths between the nodes is much smaller than the one observed in the Erdős-Renyi (ER) and BA random graphs of the same size, as highlighted below.

The final graph also exhibits a surprisingly high local cohesion. This corresponds to a relatively high value of the average clustering coefficient (denoted by \( C \)), a property which is extensively found in real networks but is rarely reproduced in models of random graphs without introducing artificial ingredients. Another remarkable property is the presence of pronounced disassortative degree-degree correlations: the average degree \( \overline{d}_k \) of the neighbours of a node with degree \( k \) depends on \( k \) and decreases as a power-law, \( \overline{d}_k \sim k^{-\nu} \), with \( \nu \approx -0.8 \). The existence of disassortative degree-degree correlations is par-
FIG. 2. Scaling of average clustering coefficient (top) and characteristic path length (bottom) for CTQW-based growths. When walks start from the first node (left panels) the average clustering coefficient increases with the network order \( N \) until it reaches a plateau around \( C \simeq 0.34 \), while the characteristic path length decreases with \( N \). If the walk starts from the last node or from a randomly selected one, then the clustering coefficient decreases over time as \( N^{-1} \) while the characteristic path length increases logarithmically with \( N \).

Initially due to the fact that the degree distribution of the resulting graphs do not have a structural cut-off [39], so that the average degree of the neighbours for a substantial fraction of the nodes (i.e., those nodes which share an edge with the super-hub), is dominated by the degree of the super-hub. For comparison, we report in the same panel the value of \( d_k \) for the BA random graph, which is practically independent of \( k \), except for the boundary effects observed for high values of \( k \).

Conversely, for selections of type (b) and (c), namely when the walk starts either from a randomly chosen node or from the last node, we obtain exponential degree distributions and small assortative degree-degree correlations (upper right and lower right panels, respectively). In this case, the degrees appear to be more homogeneous: the final graph has neither hubs nor super-hubs, it exhibits a negligible clustering coefficient and an average shortest path length (denoted by \( \ell \)) comparable to that of an ER or a BA random graph with an equal number of nodes.

For instance, in ER and BA random graphs with \( N = 3000 \) nodes, as those reported in Fig. 1, \( \ell \simeq 4.29, C \simeq 0.0035 \) and \( \ell \simeq 2.54, C \simeq 0.02 \), respectively. Instead, in the case of CTQW-based growth, when the walks start from the seed node of the growth process, then the final graph exhibits a clustering coefficient \( C \simeq 0.331 \), which is much higher than expected in a random graph, and a considerably smaller average path length \( \ell \simeq 2.41 \), which is in turn smaller than those observed in ER and BA graphs of the same size and order. Therefore, graphs grown with this method are small-worlds [40]. When the walks start from the last node, we have \( \ell \simeq 4.26 \) and \( C \simeq 0.0051 \), which are values comparable with those observed in ER and BA graphs. Choosing the starting node at random does not seem to result in a significant difference: \( \ell \simeq 4.18 \) and \( C \simeq 0.006 \). In Fig. 2 we study the scaling of \( C \) and of the average shortest path length \( \ell \) with the network order \( N \). We compare CTQW-based networks with BA scale-free graphs. Notice that, while the average clustering coefficient of a BA network decreases as \( N^{-3/4} \) [41], in CTQW-based growth with walks starting from the seed node \( C \) grows with \( N \) until it reaches a plateau around \( C \simeq 0.34 \). Similarly, the average path length decreases with \( N \), until it reaches a plateau around \( \ell \simeq 2.3 \). These scaling behaviours are mainly due to the condensation of edges around super-hubs, which favours the creation of triangles and contribute to lower the average path length. As we see from the two right panels of Fig. 2, if the
walks are started from the last node or from a randomly selected one, then the scalings of $C$ and $\ell$ are comparable with those observed in classical random graphs. The notions of assortative/disassortative degree-degree correlations, clustering coefficient and average shortest path-length are standard in the toolbox of network theory. We recall these definitions in the Appendix.

As mentioned above, CTQWs have reversible dynamics and the (von Neumann) entropy of any state during the evolution is zero. The dynamics changes if we include an interaction between the system and its environment. This introduces decoherence, a phenomenon responsible for the quantum-to-classical transition. Due to decoherence effects, the system becomes thermodynamically irreversible. There are various ways to model decoherence in quantum walks, for example, by monitoring the evolution of the system at a certain rate. The non-zero probability of performing measurements can be interpreted as a weak coupling between the quantum system and a Markovian environment (see Ref. [42] for a detailed survey of the topic). Generally, when we increase the decoherence rate, the quantum features disappear and after a critical point the behaviour of the system becomes classical. Thus, in the case of a fully decohered quantum walk, we are able to recover the familiar preferential attachment induced by classical random walks $\mathbb{G}$ – a random walk can be also obtained algorithmically from a CTQW $\mathbb{G}$. We can interpolate between these two modes by turning the level of decoherence up or down $\mathbb{G}$. For very high decoherence rates, the system will tend to remain in the initial state due to the quantum Zeno effect $\mathbb{G}$. This phenomenon can be arguably used to influence the behaviour of the degree sequence by choosing the node from which starting each walk.

The purpose of the first papers on quantum walks, written in the context of quantum computing, was to determine whether these dynamics could be used in algorithmic applications. Indeed, since then, quantum walks have been very important as a tool to design new quantum algorithms $\mathbb{G}$, both in the continuous and the discrete setting. Two reasons are behind this fact: quantum walks permit, in some cases, faster convergence towards the limiting distribution than their classical analogues; the limiting distribution – in the ways that this is defined to avoid the lack of convergence due to unitarity – often takes the shape of interference patterns that are far away from uniform. Interference is responsible for peaks in the distribution which may turn out to be useful to sample specific vertices. Therefore, we can use quantum walks to generate exotic probability distributions with the potential of highlighting certain subgraphs. The most successful application of this phenomenon is arguably perfect state transfer, where the state of a single qubit on a network of quantum spins can be transferred with complete fidelity between two particles, or periodicity, where after a given time the whole network is again in a past state. Such a behaviour gives routing without local control and it can not be found in classical random walks. With respect to the topic of the present paper, faster convergence would imply a more efficient process to simulate network growth. Of course, the process is quantum and requires a physical implementation. In addition, quantum walks have many tunable parameters as we have seen above. By changing, sometimes even minimally, the initial conditions and transition amplitudes, we can modify a walk in substantial ways and this freedom in choosing the parameters allows the growth of networks with different properties, something which is not classically available unless we steer each classical walk with extra local rules.

In this paper we have defined a single model and studied some of its basic features, but investigating the whole potential of quantum walks in network growth is a completely open direction of research. Determining the correlation between dynamical parameters and network properties is a new, unorthodox problem at the interplay of algebraic graph theory and eigen-system analysis for unitary matrices. Also, we have not considered Anderson localisation, partial decoherence, and noisy evolution. These are all physical features that can be naturally introduced into models of network growth, and that are well motivated by the available background. The effect of such features on networks may, in turn, suggest novel physical insight. Another extension of the model could be in the same spirit of Ref. [47]. The probability of attachment is determined by the outcome of a process external to the network. In our setting, the process could be a quantum walk on the integers, with the zero on the number line corresponding to the first vertex of the growth. What type of networks are grown when sampling from the interference pattern of the walk? Again, by the behaviour of the amplitudes and a specific tuning of the parameters, we should obtain networks without a known unified classical method of construction. This is left for further study.

Acknowledgments. Part of this work has been done at the Kavli Royal Society International Scientific Centre during the workshop “Function Prediction in Complex Networks” (28-29 May 2012). We are grateful to Gorjan Alagic, Andrew Childs, Vivien Kendon, and Andrea Torsello, for useful discussion.

APPENDIX

Quantum walks

A graph $G = (V, E)$ is an ordered pair, where $V(G)$ is a set whose elements are called nodes and $E(G) \subseteq V(G) \times V(G)$ is a set whose elements are called edges. Since we consider graphs growing over time, we denote by $G_t = (V, E)$ the configuration of nodes and edges at iteration $t$. Notice that the time of the growth is a discrete variable which is increased by one for each
duced by) W (G_t) = \frac{1}{2} (I_t + A (G_t) \Delta (G_t)^{-1})$, where $I_t$ is the $t \times t$ identity matrix, $A (G_t)$ and $\Delta (G_t)$ are the adjacency matrix and the degree matrix of $G_t$, respectively. Recall that $[A (G_t)]_{i,j} = 1$ if $(v_i, v_j) \in E (G_t)$ and $[A (G_t)]_{i,j} = 0$, otherwise; $[\Delta (G_t)]_{i,j} = \delta_{i,j} \cdot d (v_i)$, where $d (v_i) := |\{ v_j : (v_i, v_j) \in E (G_t) \}|$ is the degree of $v_i$, and $\delta_{i,j}$ is the Kronecker delta. The rule of the walk on the $t$-iteration graph is $W^t (G_t) \overrightarrow{v_i} \mapsto \overrightarrow{v_j}$, where $\overrightarrow{v_i}$ is an element of the standard basis of $\mathbb{R}^t$ and $\overrightarrow{v_j} \in \mathbb{R}^t$. The matrix $W^s (G_t)$ induces a distribution on the nodes of $G_t$. The j-point of the distribution corresponds to the probability of finding the walker at node $v_j$ at time $s$ if the walk started at time 0 from node $v_j$. Thus, the probability is $\mathbb{P} [i \rightarrow j, s] = |\overrightarrow{v_j} \cdot \overrightarrow{v_i}|$.

Independently of the initial state, the lazy walk $W (G_t)$ converges to a unique stationary (probability) distribution $\pi (G_t)$, such that $[\pi (G_t)]_i = d (v_i) / 2 |E (G_t)|$, for each $i = 1, ..., t$ (see, e.g., [38]). Convergence is guaranteed by the stochasticity of $W (G_t)$ and by the fact that there is a non-zero probability for the walker to remain at each node. The rate of convergence depends on the spectral gap of the adjacency matrix.

The stationary distribution of a lazy walk on $G_2$ is clearly the vector $\pi (G_2) = \frac{1}{2} (1, 1)^T$. When adding $v_3$ to $G_2$, we define $\mathbb{P} [v_1, v_3] \in E (G_3) = \mathbb{P} [v_2, v_3] \in E (G_3) = \frac{1}{2}$, which follows from $\pi (G_2)$. More generally, when adding a node $v_{t+1}$ to $G_t$, we attach $v_{t+1}$ to $m \geq 1$ nodes in $G_t$, so that the probability of attaching $v_{t+1}$ to $v_i$ reads $\mathbb{P} [v_{t+1}, v_i] \in E (G_{t+1}) = [\pi (G_t)]_i = d (v_i) / 2 |E (G_t)|$. The parameter $m$ is fixed but arbitrary. It is important to remark that $m$ is not necessarily the degree of node $v_{t+1}$ at the end of the growth process which may occur at a time $T > t$. When $m > 1$ we usually start the growth from a (connected) graph $G_m$.

This mechanism constructs exactly the scale-free graphs for the original version of the Barabási-Albert (BA) model [3]. In the BA model, bypassing the walk, a node $v_{t+1}$ of degree $m$ is added at time $t$. The probability that $v_{t+1}$ is adjacent to $v_i$ is in fact $\mathbb{P} [v_{t+1}, v_i] \in E (G_{t+1}) = [\pi (G_t)]_i = d (v_i) / 2 |E (G_t)|$, which is exactly the stationary probability of finding a lazy random walker in $G_t$ at node $v_i$.

By generalizing the above picture, given a graph on $t$ nodes, $G_t$, we define a unitary matrix $U (s, t) = e^{-i A (G_t) s}$, where $s \in \mathbb{R}^t$. Unitarity means that $U (s, t) U^\dagger (s, t) = U^\dagger (s, t) U (s, t) = I$, where $I$ is the identity matrix and $U^\dagger (s, t)$ is the adjoint of $U (s, t)$. In this case the dynamics is reversible / non-dissipative because of unitarity. The matrix $U (s, t)$ defines a continuous time quantum walk (CTQW) on $G_t$ [28]. The rule of the CTQW at the $t$-iteration is $U (s, t) |v_i \rangle \mapsto |\psi_s \rangle$, where $|v_i \rangle$ is an element of the standard basis of a formal Hilbert space $\mathcal{H} \cong \mathbb{C}^t$ and $|\psi_s \rangle \in \mathcal{H}$. The Dirac notation tells that $||\psi_s || = 1$. The probability that at time $s$ the walker visits a node $v_j$ starting in a node $v_i$ is $\mathbb{P} [i \rightarrow j, s] = ||U (s, t) |v_i \rangle |v_j \rangle|^2$. This probability is obtained by a projective measurement on $|\psi_s \rangle$: $\mathbb{P} [i \rightarrow j, s] = |\langle v_j | \psi_s \rangle|^2$. The vector (or ray) $|\psi_s \rangle$ contains the amplitudes associated to each element of the standard basis. The measurement transforms amplitudes into probabilities. According to the axioms of quantum mechanics the post-measurement state is the observed standard basis vector.

The matrix $A (G_t)$ is interpreted as the Hamiltonian inducing the quantum mechanical evolution of a particle whose degrees of freedom of the dynamics are constrained on the edges of $G_t$. Indeed, this can be seen as the operator describing the evolution of the single excitation sector of a quantum spin system (XY model) in virtue of the Jordan-Wigner transformation [22].

At the $t$-graph iteration, the mixing matrix of the CTQW at time $s$ is defined by

$$M_{s,t} = e^{i A (G_t) s} \circ e^{-i A (G_t) s} = U (s, t) \circ U (-s, t),$$

where $A \circ B |i,j \rangle := [A]_{i,j} \cdot [B]_{i,j}$ denotes the Schur-Hadamard product of two matrices $A$ and $B$. The matrix $M_{s,t}$ depends on $s$; it gives the instantaneous mixing behaviour of the walk. Formally, an element of $M_{s,t}$ is constructed by multiplying together the amplitudes obtained by evolving the system for a time $s$ in the future and for a time $s$ in the past. Differently from the case of a lazy random walk, here there is never convergence, because the dynamics is non-dissipative. For the walk, we have $||\psi_s || = ||U (s, t) |v_i \rangle|| = 1$.

We could also define an instantaneous mixing time by looking at the smallest $s \in \mathbb{R}^t$ for which the probability induced by the CTQW is close in some measure of similarity (for example, total variation distance) to the uniform or the stationary probability distribution. A possibly different growth model can be defined by making use of the distribution obtained at a given time $s$. In this case, the growth is entirely dependent on the chosen value of $s$; this could be fixed for each $t$ or as a function of $t$, for instance. To avoid a dependence on $s$, we consider a time-average of $M_{s,t}$.

The average mixing matrix is defined by taking a Cesaro mean:

$$\overline{M_t} = \lim_{s \to \infty} \frac{1}{s} \int_0^s e^{i A (G_t) s} \circ e^{-i A (G_t) s} \, ds = \sum_j E^2_j, t,$$

where $E_j$ is the $r$-th idempotent of the spectral decomposition of $A (G_t) = \sum_j \lambda_j E_j$. In other words, $E_{j,t}$ represents the orthogonal projection onto the eigenspace $\ker (\lambda_j - i)$, where $\lambda_j$ is the $j$-th eigenvalue of $A (G_t)$. The $j,t$-th entry of $\overline{M_t}$ is the average probability that a walker is found at node $v_j$ (starting at node $v_i$). Remarkably, $\overline{M_t}$ is rational [38].

In our model of growth based on CTQWs, the attaching probability is defined by $\mathbb{P} [v_{t+1}, v_j] \in E (G_{t+1}) = [\overline{M_t}]_{i,j}$, if we assume that the walker started from node
\( v_i \) at the \( t \)-th iteration of the growth process. Depending on the starting node \( v_i \), we get a different attaching probability which will be completely defined by \( G_t \). The time length of the walk is not relevant given that \( \hat{M}_t \) is defined as a limit for \( s \to \infty \).

**Algorithm.** Let \( K_n \) denote the complete graph on \( n \) vertices. This is the unique graph with \( n(n-1)/2 \) edges. Let \( [A]_i \) the \( i \)-th row of a matrix \( A \). The growth of a graph based on CTQWs starts with \( G_0 = K_n \). Then, for every \( t > m \), we sample \( m \) neighbours \( v_{j_1}, v_{j_2}, ..., v_{j_m} \) of the new node \( v_i \) from the distribution \( \hat{M}_{t-1} \) and create \( m \) edges \( \{v_i, v_{j_1}\}, \{v_i, v_{j_2}\}, ..., \{v_i, v_{j_m}\} \).

The edges are all added at the same time, after \( m \) distinct CTQWs have been performed on \( G_{t-1} \). The starting node \( v_i \) of the CTQW can be arbitrarily chosen. In the main body of the paper we report the results obtained for three different choices of the starting node, namely: a) the first node, b) the last node added to the graph and c) a different randomly sampled node for each step of the algorithm. The initial condition \( G_m = K_m \) can be also relaxed.

This simple growth algorithm, based on the sampling of new edges according to the time-average of the attaching probability distribution, suffers from the fact that the evaluation of the Cesaro mean requires the full spectrum of the adjacency matrix \( A(G_t) \). This is the critical step. In fact, although efficient schemes exist to compute the few largest eigenvalues of a symmetric matrix of size \( n \), the time complexity of the computation of the whole spectrum is \( \sim O(n^3) \). At a first analysis, it follows that the number of steps needed to sample graph of \( t \) nodes constructed with our method is of the order \( O(t^3) \). Sampling a CTQW-based graph is much more costly than sampling a BA random graph, for which the most efficient algorithm runs in \( O(t) \).

**Network metrics**

Let \( G = (V, E) \) be a graph on \( n \) nodes \( \{v_1, v_2, ..., v_n\} \). The average degree of \( G \) is \( \overline{d}(G) = \sum_{i=1}^{n} d(v_i) \). Let \( d(v_i) = k_i \) for a given node \( v_i \in V(G) \); then the average degree of the neighbours of \( v_i \) is denoted by \( \overline{d}_k \).

We say that two nodes \( v_i, v_j \in V(G) \) are connected if there is \( l \in \mathbb{Z}^+ \) such that \( [A^l(G)]_{i,j} > 0 \). Equivalently, \( v_i \) and \( v_j \) are connected if there is a walk from \( v_i \) to \( v_j \). A walk from \( v_i \) to \( v_j \) is a sequence of edges \( \{v_i = i_0, i_1, i_2, ..., i_k = v_j\} \) where the nodes are not necessarily all distinct. When the nodes of a walk are all distinct then we call it a path. The length of a path is the number of edges in the path. The distance \( d(i,j) \) between \( v_i, v_j \in V(G) \) is defined as the length of the path from \( v_i \) to \( v_j \) with the minimum number of edges. The average shortest path length of \( G \) is then defined as \( \ell := 1/n(n-1) \sum_{i,j} d(i,j) \). If there is no path containing \( v_i \) and \( v_j \) then \( d(i,j) = \infty \), by convention. Consequently, \( \ell \) is finite only for connected graphs, i.e. when every pair of nodes of the graph is connected by a path. The graphs generated by the algorithm are connected by construction. The clustering coefficient \( C_i \) of a node \( v_i \in V(G) \) is a measure of the local cohesion at \( v_i \). Taking \( k = d(v_i) \), we have \( C_i := 1/k \sum_{j} T(v_i) \), where \( T(v_i) \) is the number of different triangles containing \( v_i \). A triangle is a graph of the form \( \{v_i, v_j, v_k\}, \{v_i, v_j\}, \{v_i, v_k\}, \{v_j, v_k\} \). The clustering coefficient of \( G \) is the average of the clustering coefficients of all nodes: \( \overline{C} = \frac{1}{n} \sum_{i} C_i \) (See [39] for a general reference on these notions).

Real networks usually exhibit degree-degree correlations. For instance, in some networks (mostly social, information and communication networks) high-degree nodes are preferentially linked to other high-degree nodes, while in biological and technological networks high-degree nodes are preferentially linked to low-degree nodes [3]. The existence of degree-degree correlations can be quantified in different ways. One of the most common methods is by computing \( \overline{d}_k \) as a function of \( k \). If a graph is uncorrelated then the degree of the neighbours of a node of degree \( k \) does not depend on \( k \), and it is possible to show that \( \overline{d}_k = (k^2)/k \). In real networks we observe that \( \overline{d}_k \) depends on \( k \); if \( \overline{d}_k \) increases with \( k \), we say that the network has assortative degree-degree correlations; on the contrary, if \( \overline{d}_k \) decreases when \( k \) increases, we say that the network has disassortative degree-degree correlations. (See [50] for an in-depth discussion about degree correlations in networks.) In most real networks, \( \overline{d}_k \sim k^\nu \) (with a little abuse of notation) and the exponent \( \nu \) can be effectively used to quantify degree-degree correlations: \( \nu > 0 \) and \( \nu < 0 \) define assortative and disassortative networks, respectively [51]. The larger the modulus of \( \nu \), the stronger are the degree-degree correlations.
