(Dated: April 1, 2002)

We derive tight Bell’s inequalities for N > 2 observers involving more than two alternative measurement settings. We give a necessary and sufficient condition for a general quantum state to violate the new inequalities. The inequalities are violated by some classes of states, for which all standard Bell’s inequalities with two measurement settings per observer are satisfied.

PACS numbers: 03.65.Ud, 03.67.-a

Which quantum states do not allow a local realistic (LR) description? This question still remains open, mainly because our present tools to test local realism are not optimal. Most of Bell’s inequalities are for the case in which only two measurement settings can be chosen by each observer, e.g., the Clauser-Horne-Shimony-Holt inequality [1] (CHSH), inequalities for bipartite higher-dimensional systems [2], multipartite Bell’s inequalities [3, 4, 5, 6]. One can call such inequalities “standard” ones.

One can expect that allowing the observers to choose more than two observables should give more stringent constraints on LR models. Thus, new inequalities may extend the class of non-separable states which cannot be described by LR variables. Violation of local realism is an important ingredient for building quantum information protocols that decrease the communication complexity [7] and is a criterion for the efficient quantum information protocols that decrease the communication complexity [7].

In analogous way, one can define $A_{1234, 12}$ for replacing $A_1, A_2, B_1, B_2$ by $A_3, A_4, B_3, B_4$, respectively, and $S'$ by $S''$. Depending on the value of $m = \pm 1$ one has $(A_{12, S'} + (-1)^m A_{34, S''}) = \pm 8$, or 0. By analogy to (1) one has:

$$A_{1234, 12} \equiv\sum_{k,l=1,2} S'(k,l)(A_1 + (-1)^k A_2)(B_1 + (-1)^l B_2) = \pm 4,$$

where $S'(k,l)$ is any “sign” function, i.e., such that $S'(k,l) = \pm 1$. Since $|A_1| = |B_1| = 1$, only one term in Eq. (1) does not vanish, and its value is $\pm 4$.

After averaging over many runs of the experiment, and introducing the correlation functions $E_{ijk} \equiv \langle A_i B_j C_k \rangle_{\text{avg}}$ one obtains multisetting Bell’s inequalities. Because of the freedom to choose the sign functions $S, S', S''$, we have $(2^4)^3 = 2^{12}$ Bell’s inequalities.

We will now show that the family of $2^{12}$ inequalities can be reduced to a single “generating” one. This inequality will be obtained for non-factorable sign functions $S, S', S''$. Below we show that a choice of factorable sign function is equivalent to having a non-factorable one, and some of the local measurement settings equal. Thus, one does not need to consider factorable sign functions; one obtains inequalities for such sign functions from the generating Bell’s inequality by making some settings equal.

To show this consider function $S(k, l)$ as an example. In general $S(k, l) = a(k) + b(k)(-1)^l$, with either $a(k) = 0$ or $b(k) = 0$, and $|a(k)| + |b(k)| = 1$. If $S(k, l)$ is factorable (i.e., of the form $S(k, l) = s_1(k)s_2(l)$ with $s_1(k) = s_2(l) = \pm 1$), then either $b(k) = 0$ or $a(k) = 0$. If we choose, e.g.,
\[ b(k) \equiv 0, \text{ then the last factor on the left-hand side of Eq. (2) has the following form:} \]
\[
\sum_{l=1,2} S(k, l)(C_1 + (-1)^j C_2) \]
\[
= \sum_{l=1,2} (a(k) + b(k)(-1)^j)\left(C_1 + (-1)^j C_2\right) \]
\[
= 2a(k)C_1 + 2b(k)C_2 = 2a(k)C_1. \quad (5)
\]
The setting “2” for the third observer drops out. The final expression (5) can be also obtained, for the non-factorable \( S \), by putting \( C_1 = C_2 \). Further, if one inserts this result into Eq. (2), and, say, \( a(k) \equiv 1 \), then after the summation over \( k \) the whole term with settings 3, 4 for the first two observers vanishes. What we get is a trivial extension of the CHSH inequalities.

The whole family of multisetting Bell’s inequalities can be reduced to one “generating” inequality which is obtained for \( S, S', S'' \) non-factorable. In such cases \( a(k) = \pm \frac{1+(-1)^k}{2} \) and \( b(k) = \pm \frac{1+(-1)^k}{2} \) (the front signs are free, those in the numerators have to be different for the two functions). Any other cases are obtainable by the same method as before, one obtains an identity which

\[ \langle (C_1 + C_2)[A_1(B_1 + B_2) + A_2(B_1 - B_2)] + (C_1 - C_2)[A_3(B_3 + B_4) + A_4(B_3 - B_4)] \rangle_{\text{avg}} \leq 4. \quad (6) \]

Other inequalities can be obtained by making some settings equal. For example, the \( 3 \times 3 \times 2 \) ones can be obtained by choosing the settings 1 and 2 identical for the first two observers.

The method can be generalized for various choices of the number of parties and the measurement settings. Here we present the \( 2^{N-1} \times 2^{N-1} \times 2^{N-2} \times \ldots \times 2 \) ones.

Take the case of \( N = 4 \) observers. We start with the identity (4). One can introduce a similar identity for the settings \( \{3, 6, 7, 8\} \), for the first two observers, and \( \{3, 4\} \), for the third one. The fourth observer chooses between two settings with LR values \( D_1 \) and \( D_2 \). Applying the same method as before, one obtains an identity which generates Bell’s inequalities of the \( 8 \times 8 \times 4 \times 2 \) type:

\[
\sum_{k,l=1,2} S(k, l)(A_{1234,12} + (-1)^k A_{5678,34}) \times (D_1 + (-1)^j D_2) = \pm 64 \quad (7)
\]

where \( A_{1234,12} \) and \( A_{5678,34} \) depend on some three sign functions. One may apply this method iteratively, increasing the number of observers by one, to obtain inequalities involving exponential (in \( N \)) number of measurement settings as given above.

The inequalities are tight. We give the proof for the case \( 4 \times 4 \times 2 \) inequalities. It can be adapted to all inequalities discussed here. The left hand side of the identity (2) is equal to \( \pm 16 \) for any combination of predetermined LR results. In a 32 dimensional real space, one can build a convex polytope, containing all possible LR models of the correlation functions for the specified settings, with vertices (generators) given by the tensor products of \( v = (A_1, A_2, A_3, A_4) \otimes (B_1, B_2, B_3, B_4) \otimes (C_1, C_2) \). It has 256 different vertices. Tight Bell inequalities define the half-spaces in which is the polytope, which contain a face of it in their border hyperplane. If 32 linearly independent vertices belong to a hyperplane, this hyperplane defines a tight inequality. Half of the vertices saturate the inequality bounded by 16 and another half saturate the inequality with \( -16 \) bound. Every vertex, \( v \), saturating the first inequality, has a partner \( -v \), which saturates the other one. Any set of 128 vertices \( v \) which does not contain pairs \( v \) and \( -v \) contains a set of 32 linearly independent points (basis). Thus, each inequality is tight.

The necessary and sufficient condition for violation of multisetting Bell’s inequalities. To this end we first rederive the necessary and sufficient condition for violation of the CHSH inequality by an arbitrary two-qubit state \( |\psi\rangle \). The derivation will use certain mathematical ideas that will be later applied in the analysis of more general cases. We will use a decomposition of general mixed state of \( N \) qubits in terms of the identity operator \( \rho_0 = I \) in the Hilbert space of individual qubits and the Pauli operators \( \sigma_i \) for three orthogonal directions \( i \in \{1, 2, 3\} \), given by \( \rho = \frac{1}{2^N} \sum_{k_1, \ldots, k_N=0}^3 T_{k_1, \ldots, k_N} \sigma_{k_1} \otimes \ldots \otimes \sigma_{k_N} \). The (real) coefficients \( T_{k_1, \ldots, k_N} \), with \( k_j = 1, 2, 3 \), form the correlation tensor \( T \).

The full set of inequalities for the \( 2 \times 2 \) problem is derivable from the identity (4) and reads:

\[ \langle \sum_{k,l=1,2} S(k, l)(A_1 + (-1)^k A_2)(B_1 + (-1)^l B_2) \rangle_{\text{avg}} \leq 4. \quad (8) \]

The quantum correlation function \( E(\vec{A}, \vec{B}) \) is given by the scalar product of the correlation tensor \( T \) with the tensor product of the local measurement settings represented by unit vectors \( \vec{A} \otimes \vec{B} \), i.e. \( E(\vec{A}, \vec{B}) = \langle \vec{A} \otimes \vec{B} \rangle \cdot T \). Thus, the condition for a quantum state endowed with the correlation tensor \( T \) to satisfy the inequality (8) is that for all directions \( \vec{A}_1, \vec{A}_2, \vec{B}_1, \vec{B}_2 \) one has

\[ \left| \sum_{k,l=1,2} S(k, l)(\vec{A}_1 + (-1)^k \vec{A}_2) \otimes (\vec{B}_1 + (-1)^l \vec{B}_2) \right| \cdot |\vec{T}| \leq 4. \]

One can use the following fact. If \( \vec{X}_1 \) and \( \vec{X}_2 \) are unit vectors, then \( \vec{X}_1 + \vec{X}_2 \) and \( \vec{X}_1 - \vec{X}_2 \) are orthogonal, and \( |\vec{X}_1 + \vec{X}_2|^2 + |\vec{X}_1 - \vec{X}_2|^2 = 4. \) Therefore one can always find two orthogonal unit vectors \( \vec{X}(m) \), with \( m = 1, 2 \), given by \( \vec{X}_1 + (-1)^m \vec{X}_2 = 2x_m \vec{X}(m) \), such that the coefficients satisfy \( \sum_m x_m^2 = 1. \) Using this convention for \( \vec{X}_1 = \vec{A}_i, \vec{B}_i \) and \( x_1 = a_i, b_i \) one obtains

\[ \left| \sum_{k,l=1,2} S(k, l)a_kb_l \vec{A}(k) \otimes \vec{B}(l) \right| \cdot |\vec{T}| \leq 1. \quad (9) \]
However, $[\hat{A}(k) \otimes \hat{B}(l)] : \hat{T} = T_{kl}$ are components of the tensor $\hat{T}$ in some local coordinate system of Alice and Bob which involve vectors $\hat{A}(k)$ and $\hat{B}(l)$ as orthogonal Cartesian coordinate directional vectors. Put $\hat{A}(1) = \hat{x} = \hat{x}_1$, $\hat{A}(2) = \hat{y} = \hat{x}_2$ for Alice’s coordinate system, and similarly $\hat{B}(1) = \hat{x} = \hat{x}_1$, $\hat{B}(2) = \hat{y} = \hat{x}_2$ for Bob’s system. Thus the inequality (9) can be expressed as $\sum_{k,l=1,2} S(k,l) a_k b_l T_{kl} \leq 1$. Since one can always make the vector $(\pm a_1 b_1, \pm a_1 b_2, \pm a_2 b_2)$ parallel to any vector $(T_{11}, T_{12}, T_{21}, T_{22})$, the maximal value of the left hand side of the inequality (9) is equal to $\max \left[ \sum_{k,l=1,2} T_{kl}^2 \right]$. Thus, $\max \left[ \sum_{k,l=1,2} T_{kl}^2 \right] \leq 1$ is the necessary and sufficient condition for the inequality to hold, for any measurement settings, provided the maximization is taken over all local coordinate systems of two observers.

Consider now $4 \times 4 \times 2$ inequalities:

$$ | \langle \sum_{k,l} S(k,l)(A_{12,S'} + (-1)^k A_{34,S''})(C_1 + (-1)^j C_2) \rangle_{\text{avg}} | \leq 16, \quad (10) $$

where $S, S', S''$ are some non-factorable sign functions. The three-qubit quantum correlation functions $E(\hat{A}_i, \hat{B}_j, \hat{C}_k)$ can be represented as $(\hat{A}_i \otimes \hat{B}_j \otimes \hat{C}_k) : \hat{T}$ (with the same meaning of the symbols as before; $\hat{T}$ is now a three index tensor). Thus the condition for the $4 \times 4 \times 2$ inequalities to hold, in the quantum case, transforms into

$$ | [\hat{A}_{12,S'} \otimes (\hat{C}_1 + \hat{C}_2) + \hat{A}_{34,S''} \otimes (\hat{C}_1 - \hat{C}_2)] : \hat{T} | \leq 8, \quad (11) $$

where e.g.

$$ \hat{A}_{12,S'} = \sum_{k,l=1,2} S'(k,l)(\hat{A}_1 + (-1)^k \hat{A}_2) \otimes (\hat{B}_1 + (-1)^l \hat{B}_2). $$

To write down (11) we have used the freedom of introducing the sign changes $\hat{X}_k \rightarrow -\hat{X}_k$, compare (9). By defining $\hat{C}_1 + \hat{C}_2 = 2c_2 \hat{C}(2)$ and $\hat{C}_1 - \hat{C}_2 = 2c_1 \hat{C}(1)$ in Eq. (11), which have the properties of $\hat{X}_k(m)$, one obtains

$$ | c_2 \hat{A}_{12,S'} \otimes \hat{C}(2) : \hat{T} + c_1 \hat{A}_{34,S''} \otimes \hat{C}(1) : \hat{T} | \leq 4. \quad (12) $$

One can always choose $c_2$ and $c_1$ that maximize the left hand side. Since $\sum_{k,l=1,2} c_k^2 = 1$ this leads to the condition:

$$ [\hat{A}_{12,S'} : \hat{T}^2] + [\hat{A}_{34,S''} : \hat{T}^2] \leq 4^2, \quad (13) $$

where $\hat{T}^{(l)}$ is defined by $T_{ij}^{(l)} = \sum_{k=1}^3 C(l)_k T_{ijk}$, where in turn $C(l)_k$ is the $k$-th component of vector $\vec{C}(l)$. Note that since $\hat{C}(1)$ and $\vec{C}(2)$ are orthogonal and normalized this procedure amounts to fixing of two (new) Cartesian axes for the third observer, and accordingly transforming the correlation tensor. Since $\hat{A}_{12,S'}$ depends on different vectors than $\hat{A}_{34,S''}$, one can maximize the two terms separately. Furthermore, since the problem of maximization of $A_{nm,S'} : \hat{T}^{(l)}$ is equivalent to the $2 \times 2$ case studied earlier, the overall maximization process gives the following necessary and sufficient condition for quantum correlations to satisfy the inequality

$$ \max \sum_{x=1,2} \sum_{k,l=1,2} T_{k,l,x}^2 \leq 1. \quad (14) $$

When compared with the sufficient condition for $2 \times 2 \times 2$ inequalities to hold $\hat{T}$, namely

$$ \max \left[ \sum_{k,l=1,2} T_{kl}^2 \right] \leq 1, $$

the new condition is more demanding because the Cartesian coordinate systems denoted by the indices $k_1, l_1$ and $k_2, l_2$ do not have to be the same.

Consider now Bell’s inequalities of the type $8 \times 8 \times 2$. They are given by the average of Eq. (11) over many runs of the experiment. The generating Bell’s inequality has the form:

$$ | \langle A_{1234,12}(D_1 + D_2) + A_{5678,34}(D_1 - D_2) \rangle_{\text{avg}} | \leq 32. $$

For the quantum predictions $E(\hat{A}_i, \hat{B}_j, \hat{C}_k, \hat{D}_s)$, given by $(\hat{A}_i \otimes \hat{B}_j \otimes \hat{C}_k \otimes \hat{D}_s) : \hat{T}$, the inequality holds if

$$ \left( [\hat{A}_{1234,12} : \hat{D}(2)] : \hat{T} \right)^2 + \left( [\hat{A}_{5678,34} : \hat{D}(1)] : \hat{T} \right)^2 \leq 16^2. $$

The problem of maximization of either squared expression is similar to the problem of the $4 \times 4 \times 2$ case, where now $\hat{T}^{(l)}$ has components $T_{ij}^{(l)} = \sum_{r=1}^3 D(l)_r T_{ijr}$. We can use the same maximization algorithm as before. We get the following sufficient and necessary condition for violation of $8 \times 8 \times 4 \times 2$ inequalities

$$ \max \sum_{y=1,2} \sum_{x=1,2} \sum_{k,xy=1,2} T_{k,xy}^2 \leq 1. \quad (15) $$

Obviously in a similar way one can reach analogous conditions for violation of $2^{N-1} \times 2^{N-1} \times 2^{N-2} \times \ldots \times 2^2$ inequalities by quantum predictions.

The new conditions lead to more stringent constraints on LR description of quantum predictions than that for the standard inequalities. We now show some classes of states that violate multisetting Bell’s inequalities, but for which all standard inequalities, as of refs. [4, 5, 6] are satisfied. As a measure of the violation we use the minimal amount of white noise that must be adjoined to a quantum state for a conflict with LR prediction to disappear.

**Generalized GHZ-states:** $|\psi\rangle = \cos \alpha |00\ldots 0\rangle + \sin \alpha |11\ldots 1\rangle$. These states, although pure, satisfy all standard Bell’s inequalities for correlation functions for $\sin 2\alpha \leq 1/\sqrt{2^{N-1}}$ and $N$ odd $\geq 7$. Their non
vanishing correlation tensor components are (directions \(x, y, z\) are denoted by 1, 2, 3; the basis \(\{|0\rangle, |1\rangle\}\) is the eigenbasis of \(\sigma_z\)): \(T_{3, 3} = \cos 2\alpha\), for \(N\) odd, and 1 for \(N\) even, \(T_{1, \ldots, 1} = \sin 2\alpha\), and the components with 2\(k\) indices equal to 2 and the rest equal to 1 take the value \((-1)^k\sin 2\alpha\) (there are \(2^{N-2}\) such components). Let us assume that the last observer can choose only between settings \(x\) and \(z\). Thus, we obtain for the condition for violation of multisetting Bell’s inequality for \(N\) observers (generalization of condition (16))

\[
\sum_{k_1, \ldots, k_{N-1}=x, y} T_{k_1, \ldots, k_{N-1} x} + \sum_{k_1, \ldots, k_{N-1}=x, z} T_{k_1, \ldots, k_{N-1} z} = 2^{N-2} \sin^2 2\alpha + \cos^2 2\alpha > 1. \tag{16}
\]

Thus, the Bell’s inequalities are violated for the whole range of \(\pi/4 \geq \alpha > 0\) and for arbitrary \(N\) in contrast to the case of standard Bell’s inequalities. Note that we did not perform any maximization.

The \(|W\rangle\) state:

\[
1/\sqrt{N}(|100\ldots0\rangle + |010\ldots0\rangle + \ldots + |000\ldots1\rangle).
\]

Assume that all \(N\) observers choose between observables in the plane spanned by \(y\) and \(z\) axes. Non vanishing correlation tensor components are \(T_{x, \ldots, x} = 1\) and components, of modulus equal to \(2/N\), with only two indices \(x\) (or \(y\)) and all other indices equal to \(z\). Therefore the \(\sum_{k_1, \ldots, k_{N-1}=x, y} T_{k_1, \ldots, k_{N-1} y}\) can be at least (no optimization was made) \(1 + N\frac{4}{2N} = 3 - 2/N > 1\). Thus, if one considers a noise admixture to the \(|W\rangle\) states, in such a form that one arrives at a mixed state \(|\rho_W\rangle = (1-V)|\rho_{\text{noise}}\rangle + V|W\rangle\langle W|\), with \(\rho_{\text{noise}} = |1/2N\rangle\langle 1/2N|\), then the new inequalities show that for \(V > V_{\text{thr}} = 1/\sqrt{3-2/N}\) there is no LR description for correlations. This is a bigger range of \(V\) than for the standard correlation function Bell inequalities, compare (17).

Finally consider the state (17):

\[
|\Psi\rangle = \sqrt{1/3}(|0000\rangle + |1111\rangle + \frac{1}{2}(|1010\rangle + |0101\rangle + |0110\rangle + |1001\rangle)) \tag{17}
\]

\[
= \sqrt{2/3}|\text{GHZ}_{1234} + \sqrt{1/3}|\text{EPR}_{12}\rangle|\text{EPR}_{34}\rangle
\]

where \(|\text{EPR}\rangle = 1/\sqrt{2}(|01\rangle + |10\rangle)\) is the maximally entangled (Bell-EPR) two-qubit state. This entangled state was produced in a recent experiment [21]. Its non vanishing correlation tensor components are:

\[
T_{x, x, x, x} = T_{y, y, y, y} = T_{z, z, z, z} = 1,
\]

\[
T_{x, x, x, y} = T_{y, y, y, x} = T_{y, y, x, x} = -1/3,
\]

\[
T_{x, x, x, z} = T_{x, x, z, z} = 2/3,
\]

\[
T_{y, y, x, x} = T_{y, x, y, x} = T_{y, x, x, y} = T_{x, y, y, x} = T_{z, y, z, y} = -2/3.
\]

The left hand side of (17) is equal to 4, e.g. if all local summations are over \(x\) and \(y\). Thus the \(8 \times 8 \times 4 \times 2\) inequality is violated by the factor 2. Therefore a state \((1-V)|\rho_{\text{noise}}\rangle + V|\Psi\rangle\langle \Psi|\) gives non classical correlations for \(V > 0.5\). In contrast, standard Bell inequalities cannot be violated for \(V \leq 0.5303\).

In summary, we present multipartite Bell’s inequalities involving many measurement settings and prove that they give more stringent conditions on the possibility of a local realistic description of quantum states, than the standard Bell’s inequalities for two settings per observer.
