Abstract. We report on the detection of a strong, organized magnetic field in the helium-variable early B-type star HR 7355 using spectropolarimetric data obtained with ESPaDOnS on CFHT by the MiMeS large program. We also present results from new V-band differential photometry obtained with the CTIO 0.9m telescope. We investigate the longitudinal field, using a technique called Least-Squares Deconvolution (LSD), and the rotational period of HR 7355. These new observations strongly support the proposal that HR 7355 harbors a structured magnetosphere similar to that in the prototypical helium-strong star, \(\sigma\) Ori E.

Keywords. stars: magnetic fields - stars: rotation - stars: early-type - stars: circumstellar matter - stars: individual (HR 7355) - techniques: spectropolarimetric

1. Introduction

HR 7355 (HD 182180) is a bright B2Vn helium-strong star originally classified as a Be star due to H\(\alpha\) emission present in its spectrum (Abt \& Cardona 1984). Previous studies of this star show a \(v \sin i \sim 300\) km s\(^{-1}\) (Abt et al. 2002) with a \(P_{\text{rot}} \sim 0.52\) d (Koen \& Eyer 2002), as well as variation in helium, H\(\alpha\), and brightness, suggesting the presence of a magnetosphere (Rivinius et al. 2008). HR 7355 is the most rapidly rotating helium-strong star, rotating near its critical velocity, providing an excellent testbed for magnetospheres under the effects of rapid rotation.

2. Method

Least-Squares Deconvolution (LSD) describes the stellar spectrum as the convolution of a mean Stokes I or V profile, representative of the average shape of the line profile, and a line mask, describing the position, strength and magnetic sensitivity of all lines in the spectrum. From the LSD mean Stokes I and V profiles, we calculate the longitudinal magnetic field, \(B_\ell\):

\[
B_\ell = -2.14 \times 10^{11} \frac{\int v V(v) dv}{\lambda g \int [1 - I(v)] dv}
\] (Wade et al. 2000), where \(\lambda\) is the average wavelength and \(g\) is the average Landé factor in the mask. \(I_c\) is the continuum value of the intensity profile. The integral is evaluated over the full velocity range of the mean profile.
3. Results

We detect a strong magnetic field on HR 7355, the most rapidly rotating helium-strong star discovered thus far. A simultaneous independent confirmation of the field detection has been obtained with FORS at the VLT by Rivinius et al. 2010. The longitudinal magnetic field varies sinusoidally with the rotation period, with extrema -2 to 2.5 kG. Assuming a dipole magnetic field, the polar value of the magnetic field is \( \sim 13-17 \) kG. The photometric (brightness) light curve constructed from HIPPARCOS archival data and new CTIO measurements shows two minima separated by 0.5 in rotational phase and occurring 0.25 cycles before/after the magnetic extrema. Using the Scargle periodogram, eclipse-like photometric variations give a highly precise \( P_{\text{rot}} = 0.5214404(6) \) days. We confirm spectral variability of helium and metal lines, as well as variability of \( \text{H}_\alpha \) emission. \( \text{H}_\alpha \) emission indicates circumstellar material extending out to 5 \( R_\star \) from the star, rotating rigidly with the stellar surface. We conclude that HR 7355 is a magnetic oblique rotator with a magnetosphere, mirroring the physical picture for \( \sigma \) Ori E (Townsend et al. 2005).
