We present new lattice investigations of finite-temperature transitions for SU(3) gauge theory with \( N_f = 8 \) light flavors. Using nHYP-smeared staggered fermions we are able to explore renormalized couplings \( g^2 \lesssim 20 \) on lattice volumes as large as \( 48^3 \times 24 \). Finite-temperature transitions at non-zero fermion mass do not persist in the chiral limit, instead running into a strongly coupled lattice phase as the mass decreases. That is, finite-temperature studies with this lattice action require even larger \( N_T > 24 \) to directly confirm spontaneous chiral symmetry breaking.

SU(3) gauge theory with \( N_f = 8 \) massless fundamental flavors is currently the subject of considerable interest, both as a quantum field theory exhibiting strongly coupled dynamics significantly different from QCD, and also as the basis for models of new strong dynamics producing a standard-model-like 125-GeV Higgs particle. We can only include here an incomplete collection of references to recent investigations employing both continuum and lattice methods. 1–11

In this work we attempt to confirm the conventional wisdom that chiral symmetry breaks spontaneously for \( N_f = 8 \), which would rule out the existence of an 8-flavor conformal IR fixed point (IRFP). However, this requires extrapolating to the massless chiral limit, and we are unable to establish that chiral symmetry breaking persists in that limit.

Previous lattice studies have explored the discrete \( \beta \) function of the 8-flavor system, denoted \( \beta_s(g^2) \) for scale change \( s \). 1,10,11 An IRFP would correspond to \( \beta_s(g^2) = 0 \), and no such zero has been observed. In fact, the \( \beta \) function was found to be monotonic throughout the ranges of couplings explored: \( g^2_{SF} \lesssim 6.6 \) in the Schrödinger functional scheme, 1,10 and \( g^2_c \lesssim 14 \) in gradient flow schemes with \( c = 0.25 \). The last result is the most relevant to this work, since we use the same lattice action with nHYP-smeared staggered fermions and both fundamental and adjoint plaquette terms with couplings related by \( \beta_A/\beta_F = -0.25 \). This enables us to relate our bare lattice couplings \( \beta_F \) to renormalized \( g^2_c \). This work is part of ongoing investigations by the Lattice Strong Dynamics (LSD) Collaboration, using this action to extend the USBSM project. 13

The non-observation of an IRFP by lattice studies of the discrete \( \beta \) function does not guarantee that the 8-flavor theory exhibits spontaneous chiral symmetry breaking.
breaking. On their own such calculations cannot rule out the possibility that the system flows to an IRFP at a stronger coupling. In fact, the non-perturbative $\beta_s(g^2 \approx 14)$ is comparable to the four-loop $\overline{\text{MS}}$ prediction, which does possess an IRFP at $g^2_{\overline{\text{MS}}} \approx 19.5$. To exclude such behavior one must demonstrate that the massless system spontaneously breaks chiral symmetry at some $g^2$ for which the $\beta$ function is still non-zero. Here we attempt to do this by studying chiral symmetry breaking at finite temperature $T = 1/(aN_T)$ and non-zero fermion mass $a_m$, where “$a$” is the lattice spacing and the lattice volume is $L^3 \times N_T$ with $L/N_T = 2$. We work with fixed $N_T = 20$ and 24 for small $0.0025 \leq a_m \leq 0.01$, and extrapolate $a_m \to 0$ to investigate the massless chiral limit.

The chiral extrapolation is crucial since $a_m > 0$ explicitly breaks chiral symmetry and can even produce QCD-like scaling that disappears as $a_m$ decreases. This behavior was observed in previous studies (using the same lattice action) that considered $a_m \geq 0.005$ and $N_T \leq 20$. As shown in the left plot of Fig. 1, QCD-like scaling between $12 \leq N_T \leq 16$ for $a_m \geq 0.01$ is lost at $a_m = 0.005$ where the finite-temperature transitions merge with bulk (zero-temperature) transitions into the $S^4$ lattice phase in which the single-site shift symmetry ($S^4$) of the staggered action is spontaneously broken. In IR-conformal systems such behavior persists in the chiral limit as $N_T \to \infty$, whereas for chirally broken systems the massless transitions must move to $\beta_F(c) \to \infty$ as $N_T \to \infty$.

The right plot of Fig. 1 shows our new results, which include smaller $a_m = 0.0025$ on $40^3 \times 20$ and $48^3 \times 24$ lattices. These $N_T = 20$ and 24 are extraordinarily large compared to typical lattice QCD calculations. Unfortunately they do not suffice to establish spontaneous chiral symmetry breaking. At $a_m = 0.0025$ the $N_T = 20$ finite-temperature transition also merges with the bulk transition into the $S^4$ lattice phase. Even the $N_T = 24$ finite-temperature transitions will clearly run into the $S^4$ phase at non-zero mass, rather than reaching the chiral limit.

In Fig. 2 we present some results for observables that have proven useful to

![Fig. 1. Left: Previous $N_f = 8$ studies found that the finite-temperature transitions merge with zero-temperature bulk transitions into the $S^4$ lattice phase as the fermion mass $a_m$ decreases. Right: Our new results produce the same behavior at smaller masses on larger lattice volumes, implying that $N_T > 24$ is required to establish spontaneous chiral symmetry breaking for $N_f = 8$. This plot zooms in on the weak-coupling regime to the right of the $S^4$ phase.](image-url)
identify both bulk and finite-temperature transitions: the Wilson-flowed Polyakov loop $PL_W$ and the massless Dirac eigenvalue spectrum $\rho(\lambda)$. $PL_W$ is a modern adaptation of the RG-blocked Polyakov loop investigated in previous studies, which significantly improves signals of the finite-temperature transition without altering its location. It is trivial to measure the Polyakov loop as a function of Wilson flow time $t$, and sufficiently large $t$ produces a clear contrast between confined systems with small $PL_W$ and deconfined systems with large $PL_W$. This is shown in the left plot of Fig. 2 for $N_T = 20$ and $t = (0.3 N_T)^2 / 8$ corresponding to $c = \sqrt{5} / N_T = 0.3$. As the fermion mass decreases from $am = 0.01$ the finite-temperature transition in $PL_W$ steadily sharpens and moves to stronger coupling, merging with the bulk transition into the $S^4$ phase at $am = 0.0025$ as in Fig. 1.

The right plot of Fig. 2 shows the eigenvalue spectrum $\rho(\lambda)$ for a subset of the $N_T = 20$ ensembles with $am = 0.005$, clearly contrasting the three different phases we can observe for this mass. At the weakest coupling shown, $\beta_F = 4.8$, the system is deconfined and chirally symmetric, with $\rho(0) = 0$ and a gap below the smallest eigenvalue $\lambda_0 > 0$. The gap grows at even weaker couplings that are not included in this plot. Moving to stronger couplings, at $\beta_F = 4.7$ we observe the expected chiral symmetry breaking, with $\rho(0) \neq 0$ and a small slope $d\rho / d\lambda$. That is, we find $4.7 < \beta_F^{(c)} < 4.8$ for the $N_T = 20$ transition with $am = 0.005$, slightly sharper than the signal in $PL_W$. However, at the strongest coupling shown, $\beta_F = 4.5$, chiral symmetry breaking is lost ($\lambda_0 > 0$) and the system exhibits the “soft edge” $\rho(\lambda) \propto \sqrt{\lambda - \lambda_0}$ characteristic of the $S^4$ phase. Finally, $\beta_F = 4.6$ appears to exhibit partial features of both the chirally broken and $S^4$ phases, with $\rho(0) \neq 0$ but a much larger slope approaching the square-root behavior of the soft edge.

While this finite-temperature study with $N_T = 20$ and 24 is not able to establish spontaneous chiral symmetry breaking for $N_f = 8$, it is only part of ongoing inves-
tigations by the LSD Collaboration that primarily focus on the zero-temperature hadron spectrum, and in particular the scalar Higgs particle. When that work is finalized, combining these complementary studies of the discrete $\beta$ function, finite-temperature transitions, and hadron spectrum, all using the same lattice action, will shed further light on $N_f = 8$ and its phenomenological viability as the basis for new strong dynamics beyond the standard model.

Acknowledgments: We thank the other members of LSD for continuing collaboration on $N_f = 8$. AH and DS are grateful for the hospitality of the Aspen Center for Physics, supported by the U.S. National Science Foundation under Grant No. PHYS-1066293. This work was supported by Lawrence Livermore National Laboratory (LLNL) LDRD 13-ERD-023 (ER) and by the U.S. Department of Energy (DOE), Office of Science, Office of High Energy Physics, under Award Numbers DE-SC0010005 (AH), DE-SC0008669 (DS) and DE-SC0009998 (DS). Numerical calculations were carried out through LLNL Institutional Computing Grand Challenge program allocations on the LLNL BlueGene/Q (rzuseq and vulcan) supercomputer and on the DOE-funded USQCD facilities at Fermilab.
