Abstract

Key message We found two loci on chromosomes 2BS and 6AL that significantly contribute to stripe rust resistance in current European winter wheat germplasm.

Abstract Stripe or yellow rust, caused by the fungus *Puccinia striiformis* Westend f. sp. *tritici*, is one of the most destructive wheat diseases. Sustainable management of wheat stripe rust can be achieved through the deployment of rust resistant cultivars. To detect effective resistance loci for use in breeding programs, an association mapping panel of 230 winter wheat cultivars and breeding lines from Northern and Central Europe was employed. Genotyping with the Illumina® iSelect® 25 K Infinium® single nucleotide polymorphism (SNP) genotyping array yielded 8812 polymorphic markers. Structure analysis revealed two subpopulations with 92 Austrian breeding lines and cultivars, which were separated from the other 138 genotypes from Germany, Norway, Sweden, Denmark, Poland, and Switzerland. Genome-wide association study for adult plant stripe rust resistance identified 12 SNP markers on six wheat chromosomes which showed consistent effects over several testing environments. Among these, two marker loci on chromosomes 2BS (*RAC875_c1226_652*) and 6AL (*Tdurum_contig29607_413*) were highly predictive in three independent validation populations of 1065, 1001, and 175 breeding lines. Lines with the resistant haplotype at both loci were nearly free of stripe rust symptoms. By using mixed linear models with those markers as fixed effects, we could increase predictive ability in the three populations by 0.13–0.46 compared to a standard genomic best linear unbiased prediction approach. The obtained results facilitate an efficient selection for stripe rust resistance against the current pathogen population in the Northern and Central European winter wheat gene pool.

Introduction

Stripe or yellow rust (Puccinia striiformis) is a major disease in bread wheat (Triticum aestivum L.) production under temperate climatic conditions or at high altitudes with a significant impact on grain yield and end-use quality characteristics (Singh et al. 2016). It is caused by Puccinia striiformis Westend f. sp. tritici (Pst), which is a biotrophic and heteroecious fungus. The pathogen is a common fungal disease of cereals and grasses, and various Berberis species can serve as alternate hosts (Hovmøller et al. 2011). Depending on various factors such as disease duration, infection stage, speed of disease development, susceptibility of cultivars, and favorable climatic conditions, yield reductions range from 10 to 40% (13% on average, Laidig et al. 2021) and can be as high as 100% if infection occurs at the seedling stage and persists until maturity (Afzal et al. 2007; Pradhan et al. 2020). Although stripe rust can be controlled with fungicides, economical, sustainable, and environmentally sound management of this disease is needed. Breeding of resistant cultivars can be facilitated through identification, introduction, and subsequent selection of effective rust resistance genes during breeding cycles in wheat.

Fungal disease resistance genes in crop plants can generally be divided into all-stage resistance (ASR) genes and adult plant resistance (APR) genes. ASR genes are effective against avirulent pathotypes at all growth stages of the plant. The pathogen is a common fungal disease of cereals and grasses, and various Berberis species can serve as alternate hosts (Hovmøller et al. 2011). Depending on various factors such as disease duration, infection stage, speed of disease development, susceptibility of cultivars, and favorable climatic conditions, yield reductions range from 10 to 40% (13% on average, Laidig et al. 2021) and can be as high as 100% if infection occurs at the seedling stage and persists until maturity (Afzal et al. 2007; Pradhan et al. 2020). Although stripe rust can be controlled with fungicides, economical, sustainable, and environmentally sound management of this disease is needed. Breeding of resistant cultivars can be facilitated through identification, introduction, and subsequent selection of effective rust resistance genes during breeding cycles in wheat.

Based on the “Catalogue of Gene Symbols for Wheat” available at (https://wheat.pw.usda.gov/GG3/WGC), 85 formally named and more than 300 tentatively named genes or QTL located on different wheat chromosomes have been reported for stripe rust resistance (Maccarferri et al. 2015; Bulli et al. 2016; McIntosh et al. 2017; Mu et al. 2020). Of these, only a few genes, namely Yr5/YrSP and Yr7 (Marchal et al. 2018), Yr15 (Klymiuk et al. 2018), Yr10 (Liu et al. 2014), Yr18 (Krattinger et al. 2009), Yr27 (Athiyanann et al. 2022), Yr36 (Fu et al. 2009), Yr46 (Moore et al. 2015), and YrAS2388R (Zhang et al. 2019) have been cloned and functionally characterized. Some chromosomes, such as 1B, 2A, 2B, and 7B, harbor a substantial number of genes or genes with effective ASR genes is recommended to achieve commercially acceptable levels of resistance (Bariana 2003; Gessese et al. 2021).

The use of fungicides and the cultivation of resistant varieties has prevented devastating epidemics in Europe in the past, while genetic resistance is still the most effective and sustainable approach. In Europe, stripe rust occurred infrequently due to the use of a few key resistance genes with long-term efficacy such as Yr1, Yr2, Yr3, Yr4, Yr6, Yr9, Yr15, Yr17, Yr25, and Yr32 (Hovmøller 2007; Hovmøller et al. 2016). In 2011, “Warrior,” a new virulent stripe rust strain from the near-Himalayan region (Hovmøller et al. 2016), emerged simultaneously in several European countries and spread rapidly across much of the continent. According to monitoring by the Julius Kühn Institute (JKI, Germany), the Pst race “Warrior (-)” dominates the European yellow rust population, followed by the races “Triticale2015” and the original “Warrior,” as well as a new race “PstS15,” which was first discovered in 2020 (Flath et al. 2021). It seems that only a few resistance genes, including Yr5, Yr10, Yr15, and Yr27, are still effective against these races in European wheat (K. Flath 2022, JKI, personal communication).

The chromosomal positions of several stripe rust resistance genes and quantitative trait loci (QTL) were determined using classical mapping approaches (Tsomin et al. 1990; Bariana and McIntosh 1993; Michelmore et al. 1991; Xu et al. 2008; Edae et al. 2016; Gessese et al. 2021) and, more recently, using genome-wide association studies (GWAS) (Bouvet et al. 2021; Rollar et al. 2021). To complement traditional QTL mapping, GWAS combined with high-density SNP genotyping have been successfully used as powerful tools for discovery of stripe rust resistance loci in a global collection of winter wheat accessions (Bulli et al. 2016), spring wheat landraces (Kankwatsa et al. 2017), diverse Indian spring wheat cultivars (Kumar et al. 2020), US winter wheat cultivars and breeding lines (Mu et al. 2020), elite wheats of the International Maize and Wheat Improvement Center (CIMMYT) (Juliana et al. 2018), European winter wheat (Miedaner et al. 2019), and modern Chinese wheat (Jia et al. 2020).
QTL that confer different types and degrees of resistance to stripe rust (Maccaferri et al. 2015). Although some race-nonspecific resistance genes are effective and durable against the new _Pst_ races (Abou-Zeid and Mourad 2021), virulent _Pst_ races have emerged against most _Yr_ genes, rendering them ineffective (Maccaferri et al. 2015). Thus, continued efforts are needed to characterize new resistance sources for maintaining or increasing resistance levels. Compared to wild relatives of wheat, identification and characterization of resistance genes from landraces and cultivated genotypes is more preferable due to the absence of undesirable agronomic traits and chromosomal linkage drags in the latter (Burt et al. 2014; Gessese et al. 2021). The selection and combination of resistance genes already present in the advanced breeding pool allows for a faster development of new resistant varieties.

Classical phenotypic selection for _Pst_ resistance is resource demanding, and its success strongly depends on environmental factors. The prediction of breeding values using molecular markers has become a promising approach to facilitate genomic selection. Marker-based prediction of breeding values can be categorized into marker-assisted selection (MAS), which makes use of a preselected set of markers associated with important resistance genes, and genomic selection (GS), which is based on genome-wide marker information. Previous studies have shown the potential of both MAS and GS for the prediction of _Pst_ resistance, but comparisons of predictive abilities of the two approaches do not yet allow a clear conclusion about the optimal prediction method (Juliana et al. 2017; Muleta et al. 2017; Beukert et al. 2020b).

Compared to previous studies (Miedaner et al. 2019; Beukert et al. 2020a; Bouvet et al. 2021; Rollar et al. 2021) that used European winter wheat materials released in a broader time period, the present work identified QTL for stripe rust resistance in a collection of 230 current Central and Northern European winter wheat, examined the effects of these QTL in practical breeding programs and suggested prediction models for breeding cultivars with improved stripe rust resistance. Selection and combination of alleles already present in the advanced breeding pool is essential for improving durable resistance to stripe rust and for developing new wheat varieties. Specifically, the objectives of our study were to (1) perform GWAS in modern wheat germplasm using disease responses to current _Pst_ populations assessed in field trials, (2) identify the sources of effective resistance alleles and associated QTL for use in breeding programs, (3) validate QTL in breeding materials, (4) compare the resistance loci identified in this study with previously reported _Yr_ genes and QTL. Our results will help to understand the genetic basis of stripe rust resistance in Northern and Central European winter wheat and facilitate improvement of stripe rust resistance through MAS and GS.

### Materials and methods

#### Plant materials and stripe rust assessment

With the aim to capture wide genetic variability across Europe, we selected a population of 230 winter wheat cultivars and breeding lines for the GWAS. Using the breeder’s knowledge and the coefficient of determination algorithm (Akdemir et al. 2021), we selected genotypes from Germany, Austria, Norway, Sweden, Denmark, Poland, and Switzerland comprising 157, 50, 14, 4, 3, 1, and 1 genotype(s), respectively (Table S1).

The 230 genotypes of the association panel were evaluated for stripe rust resistance at the adult plant stage in field experiments. Each entry was sown in two-row microplots 0.5–1.5 m long and 0.17–0.3 m wide with approximately 50 grains per row in October each year. Field trials were carried out at Lemgo and Lenglern in Germany, and in Tulln and Reichersberg in Austria in 2020 and 2021 (Table S2). We used non-replicated trials in favor of multiple sites, except for Tulln, where a randomized complete block trial with two replicates was conducted. To validate the results of this study, using same sowing conditions, two _F_₆ populations of 1065 and 1001 German breeding lines from two consecutive breeding cycles were evaluated in Lemgo in 2020 and 2021, respectively, and another independent population of 175 breeding lines was evaluated in Lenglern in 2021. Field responses to either natural or artificial inoculation with _Pst_ isolates (Table S1) were recorded between plant heading (Zadoks 50) and grain filling (Zadoks 80) stages when most flag leaves of susceptible controls had disease severity of at least 50%. Disease severity as a percentage of infected leaf area was scored 3–5 times in June using the modified Cobb scale (Peterson et al. 1948) and means for the recorded scores for stripe rust were used in the analyses.

#### Statistical analysis

Implementation of the coefficient of determination algorithm for selection of the genotypes was done in R package "TrainSel" (R Core Team, 2017). After testing several transformation methods to meet the assumption of normality of residuals, the arc sine square root transformation method (Maccaferri et al. 2015) was chosen to prepare phenotypic data for association analysis. Analyses of variance (ANOVA) and estimation of adjusted means across environments were conducted using "PROC GLM" of the SAS statistical package v.9.4 (SAS Institute, Cary, USA) by applying the following model:

\[ y_{ij} = \mu + g_i + t_j + e_{ij} \]
where $y_{ij}$ is the phenotypic value of genotype $i$ in trial $j$, $\mu$ is the overall mean, $g_i$ is the fixed effect of genotype $i$, $t$ is the random effect of trial/environment $j$ and $e_{ij}$ is the random error, which was confounded with genotype × environment effects. The heritability coefficient was estimated according to the formula

$$h^2 = \frac{\sigma_G^2}{\sigma_G^2 + \sigma_e^2 / T}$$

where $\sigma_G^2$ is the genotypic variance, $\sigma_e^2$ is the residual variance, and $T$ is the number of trials. Variance components for estimating $h^2$ were derived from the above-mentioned model assuming a random genotypic effect.

### SNP genotyping

Genomic DNA of each genotype belonging to the association panel and validation populations was extracted from young leaf tissue according to the procedure of Plaschke et al. (1995). Genotyping was performed using the 25 K Infinium iSelect array (TraitGenetics, Seeland OT Gatersleben, Germany), which is an extension of 20 K array (Arif et al. 2021) plus 5000 Axiom array markers and candidate genes. SNP markers on the 25 K array were selected from the 90 K Infinium array, the 35 K Axiom wheat breeder array, and two proprietary TraitGenetics wheat arrays (135 K Axiom and 12 K Infinium). These markers were also selected based on the analysis of more than 2500 wheat cultivars, accessions and breeding lines according to the quality of performance on each analysis platform, their polymorphism information content (LD to flanking SNPs, MAF) and their position on the wheat reference genome (Dr. Jörg Plieske, TraitGenetics, personal communication). The physical position of the markers was determined by BLAST and e-value cut off for the highest probability match using the published genome sequence of Chinese Spring (IWGSC RefSeq v1.0). SNPs were filtered to avoid producing redundant genotyping information. The monomorphic SNPs and those with more than 10% missing values and minor allele frequency of less than 5% were excluded from further analysis using the "synbreed" package (Wimmer et al. 2012) to determine the possible number of subpopulations using the $\Delta K$ ad hoc statistic. The best K value representing the optimal number of clusters in the populations was estimated as $\Delta K$ based on the rate of change of log-likelihood of data between successive values, as described by Evanno et al. (2005). Population structure was also analyzed by principal component analysis (PCA) to distinguish different groups using the "PROC PCA" in the SAS statistical package.

### Association mapping

Linkage disequilibrium (LD) between markers was estimated for the association mapping panel using observed versus expected allele frequencies in TASSEL 5.2.78 (Bradbury et al. 2007). LD decay was measured as the distance at which the average $R^2$ value between pairwise SNPs fell to half its maximum value. Both Bayesian clustering method of STRUCTURE and PCA revealed a population structure in the panel. Marker-trait association in each environment and across environments were carried out using a mixed linear model that accounts for population structure ($Q$) and kinship matrix ($K$). The model can describe as follows:

$$y = X\beta + Zu + e,$$

where $y$ is the vector of observations, $\beta$ is a vector containing fixed effects for genetic markers and population structure ($Q$), $u$ is a vector of random additive genetic effects from multiple background QTL with $u \sim N(0, \sigma_G^2 K)$, $X$ and $Z$ are the design matrices, and $e$ is a vector of random residuals with $e \sim N(0, \sigma_e^2 I)$. To provide the adjusted p-values, the false discovery rate (FDR) was calculated, using a threshold of $< 5\%$, with the "q-value" package in R (R Core Team, 2017). To evaluate the performance of the models and appropriate thresholds, QQ plots drawn by TASSEL were inspected. Associations of SNP markers with stripe rust severity in each environment and across environments are represented as Manhattan plots. The physical position of significantly associated markers across environments was compared to previously published $Yr$ genes and QTL using the “Catalogue of Gene Symbols for Wheat” (https://wheat.pw.usda.gov/GG3/WGC) and an integrated map for chromosomal positions of loci associated with reactions to Pst constructed by Bulli et al. (2016) and Maccaferri et al. (2015).

### Validation of associated markers

To detect allelic effect of associated SNP markers identified by GWAS in validation populations, the Student’s $t$-test was applied for evaluating statistically significant differences ($P \leq 0.05$) between means of two allelic groups belonging to each locus of interest for disease severity.
Putative candidate gene identification

Candidate genes for validated loci were identified by blasting the sequences of the markers on the corresponding chromosomes of the International Wheat Genome Sequencing Consortium RefSeq v2.1 (https://urgi.versailles.inrae.fr/blast_iwgsc/dbgroup=wheat_iwgsc_refseq_v2.1_chromosomes&program=blastn; Zhu et al., 2021) to retrieve the gene identifiers within a window of 2 Mb (1 Mb upstream and downstream) from the peak of each targeted marker. Gene ontology terms were obtained from EnsemblPlants using the biomaRt package (Durinck et al. 2009).

Prediction of stripe rust resistance

The predictive ability of different linear regression models was evaluated using adjusted phenotypic mean values after arc sine square root transformation as response variable. Only a common set of SNP markers that remained after filtering in the GWAS panel and the three validation panels was considered for prediction. Linear regression using the ordinary least squares (OLS) method was performed using the "stats" package (R Core Team 2017). Following the matrix notation of the GWAS model shown above, the OLS model was fitted considering only fixed marker effects (\( \beta \)) and a random error (\( e \)). Genomic best linear unbiased prediction (GBLUP) models were fitted with rrBLUP (Endelman and Weisberg 2019). Predictive ability was defined as the correlation between estimated breeding values and observed phenotypic values. Predictive ability was first estimated within the GWAS panel and the three validation panels using a five-fold cross-validation with 200 replications (\( N_{\text{training}} = 184, N_{\text{test}} = 46 \)). The predictive ability of these models was also evaluated in the three independent validation populations using the complete GWAS panel for model training.

Results

Phenotypic evaluation for stripe rust

Depending on the environmental conditions and the \( Pst \) pathotypes present in the different field trials, a wide variation was observed for the severity of stripe rust in the panel in each environment (ranging from 0 to 87.5%). The four breeding lines TS085, TS175, TS185, and TS220 and three cultivars TS140 (Gentleman), TS173 (Tobak) and TS195 (Sinatra) from Germany and the cultivar TS027 (Mariboss) from Norway were completely resistant in different field trials and across environments (Table S1). The cultivars TS012 (Rida) from Norway and TS014 (Akteur) from Germany were highly susceptible in this panel (Table S1). Stripe rust severity was left skewed in each experiment and for means across experiments (Table 1; Fig. S1.A). Significant (\( P < 0.05 \)) and positive correlations ranging from 0.57 to 0.76 were observed between all pairs of test environments (Table 2), with the highest correlation (0.76) between Lemgo 20 and Lemgo 21, while the lowest correlation (0.57) was found between Lenglern 21 and Reichersberg 21.. Normality of residuals was achieved by applying the arc sine square root transformation method (Fig. S1.B). ANOVA revealed significant differences (\( P < 0.01 \)) among the genotypes. The estimate of genetic variance (\( \sigma_g^2 = 0.026 \)) contributed to a high broad-sense heritability for stripe rust resistance (\( h^2 = 0.87; \sigma_q^2 = 0.017; \sigma_e^2 = 0.019 \)).

Genotyping, population structure and LD decay

After marker filtering, 8812 informative and polymorphic SNP markers (Table S3) with an average minor allele frequency of 0.26 were used for analyzing population structure, LD, and genetic association. Of these, 3390, 3977, and 1445 markers belonged to subgenomes A, B, and D, respectively, with most markers (683) found on chromosome 5B and the fewest markers (70) on chromosome 4D. All SNPs were physically anchored to the reference sequence of Chinese Spring wheat.

Two subpopulations were detected in the winter wheat panel of 230 genotypes (Fig. S2). The number of subpopulations (\( K \)) was estimated based on the rate of change of the log-likelihood of the data between successive \( K \) values. In the plot of \( K \) versus \( \Delta K \), a reduction in the slope was observed at \( \Delta K = 2 \) (Fig. S2A). Therefore, the panel was divided into two subgroups based on the corresponding population membership coefficients (\( Q \)) of the individuals, with subgroup 1 containing 92 genotypes mainly from Austria and the cultivar TS027 (Mariboss) from Norway were completely resistant in different field trials and across environments (Table S1). The cultivars TS012 (Rida) from Norway and TS014 (Akteur) from Germany were highly susceptible in this panel (Table S1). Stripe rust severity was left skewed in each experiment and for means across experiments (Table 1; Fig. S1.A). Significant (\( P < 0.05 \)) and positive correlations ranging from 0.57 to 0.76 were observed between all pairs of test environments (Table 2), with the highest correlation (0.76) between Lemgo 20 and Lemgo 21, while the lowest correlation (0.57) was found between Lenglern 21 and Reichersberg 21.. Normality of residuals was achieved by applying the arc sine square root transformation method (Fig. S1.B). ANOVA revealed significant differences (\( P < 0.01 \)) among the genotypes. The estimate of genetic variance (\( \sigma_g^2 = 0.026 \)) contributed to a high broad-sense heritability for stripe rust resistance (\( h^2 = 0.87; \sigma_q^2 = 0.017; \sigma_e^2 = 0.019 \)).

Genotyping, population structure and LD decay

After marker filtering, 8812 informative and polymorphic SNP markers (Table S3) with an average minor allele frequency of 0.26 were used for analyzing population structure, LD, and genetic association. Of these, 3390, 3977, and 1445 markers belonged to subgenomes A, B, and D, respectively, with most markers (683) found on chromosome 5B and the fewest markers (70) on chromosome 4D. All SNPs were physically anchored to the reference sequence of Chinese Spring wheat.

Genotyping, population structure and LD decay

After marker filtering, 8812 informative and polymorphic SNP markers (Table S3) with an average minor allele frequency of 0.26 were used for analyzing population structure, LD, and genetic association. Of these, 3390, 3977, and 1445 markers belonged to subgenomes A, B, and D, respectively, with most markers (683) found on chromosome 5B and the fewest markers (70) on chromosome 4D. All SNPs were physically anchored to the reference sequence of Chinese Spring wheat.
and subgroup 2 containing 138 genotypes mainly from Germany, Norway, Sweden, Denmark, Poland, and Switzerland (Fig. S2B). PCA also classified the panel into two subpopulations (Fig. 1). PC1 and PC2 accounted for 20% and 10% of the total marker-based variation, respectively. In the LD analysis (Fig. S3), patterns between significantly associated markers were determined using the squared Pearson correlation coefficient ($R^2$) between SNP markers as a function of physical map position between markers. As shown in the scatter plot (Fig. S3), the strength of LD due to linkage decreases as the physical distance between SNPs in the genome increases. LD decay reached $R^2 = 0.2$ at 200 Mb.

**GWAS and candidate genes for stripe rust resistance**

GWAS using a mixed linear model identified 67 different loci on 12 wheat chromosomes, namely 1A, 2A, 2B, 3A, 3B, 4B, 5B, 5D, 6A, 7A, 7B, and 7D which were significantly associated with stripe rust disease severity assessed in at least one trial (Table 3; Fig. S2). The QQ plots evaluating the performance of the mixed linear models indicated a high corrective effect of the GWAS model (Fig. S4). The percentage of explained phenotypic variance ($R^2$) of the associated markers ranged from 5 to 11%, while the effect size of those markers ranged from −0.37 to 0.28 (Table 3). The strongest association ($R^2 = 11\%$, $p$ value = 0.0001) was found for the SNP markers Jagger_c1423_102 and GENE-4167_145 on chromosome 6A in Lemgo 21 (Table S4). Resistant allele G at marker locus IAAV1743 and susceptible allele G at marker locus RAC875_c1226_652 both on chromosome 2B showed the maximum effects (0.37 and 0.28, respectively) on stripe rust severity identified in Lemgo 20 and Reichersberg 21 field trials, respectively (Table S4). Of the 67 markers, 12 SNP markers on chromosomes 2B, 4B, and 6A, 7A, 7B, and 7D displayed significant associations for means across environments (Table 4). Four SNP markers on chromosomes 2B (Jagger_c6853_60), 7A (BS00093016_51), 7B (AX-95154562), and 7D (AX-94720261) were significantly associated solely with the average stripe rust severity across all field trials (Table 3). In addition, eight SNP markers were

### Table 2

Phenotypic correlations of stripe rust severity scores (based on mean values) of the 230 lines in the GWAS panel among field trials

**Fig. 1** Principal component analysis showing two groups corresponding to two subpopulations in STRUCTURE analysis. Group 1 consisted of 92 Austrian breeding lines and cultivars, which were separated from the other 138 genotypes from Germany, Norway, Sweden, Denmark, Poland, and Switzerland (Group 2).
found to be common (Table S3; Table 4) in at least two environments on chromosomes 2B (RAC875_c1226_652, IAAV1743, Ra_c6266_136), 4B (AX-94684920), and 6A (Tdurum_contig29607_413, Jagger_c1423_102, GENE-4167_145, BS00040814_51).

Notably, the association of only two markers, namely RAC875_c1226_652 on chromosome 2B and Tdurum_contig29607_413 on chromosome 6A, with stripe rust resistance were validated by Student’s t-test (P ≤ 0.001) in three validation populations of 1065, 1001, and 175 breeding lines assessed for disease severity in Lemgo, Germany, in 2020 and 2021 and in Lenglern, Germany, in 2021. For the marker RAC875_c1226_652, the G allele and for the marker Tdurum_contig29607_413, the T allele contributed to a 10–18% and 8–17% reduction in stripe rust disease severity in the validation populations, respectively (Fig. 2). Lines in the validation that harbored the resistance improving alleles at both markers (Fig. 2), showed a highly to completely resistant phenotype (0–1.6% stripe rust severity) compared to haplotypes with the “susceptible” alleles (10–35% stripe rust severity). Interestingly, only one breeding line (TS128) in the GWAS panel possessed this allele combination.

To further investigate the validated loci, sequences of the two SNP markers RAC875_c1226_652 and Tdurum_contig29607_413 were aligned to the physical map of the reference genome to search for annotated genes. As a result, 20 to 68 putative candidate genes (Table S5) were identified in a 2-Mb physical interval around the peak markers on chromosomes 2B and 6A, respectively. The genes TraesCS2B02G182800 and TraesCS6A02G399600, which were directly tagged by these markers, encode a putative disease resistance protein RGA4 (LOC123044110), BST_chr2B_nlr_143 and the E3 ubiquitin protein ligase RHB1A (LOC123129052), respectively, and are known to be involved in disease resistance and defense mechanisms in wheat.

Finally, the corresponding physical interval of the associated loci for means across environments identified in the present study were compared with previously reported Yr genes and QTL (Table S6). The physical interval of the compared QTL showed overlap with eighteen QTL and six genes including Yr27, Yr5, Yr44, YrSp, Yr62, and Yr18.

### Predicting resistance to stripe rust

The potential of MAS and GS to select for 
Pst resistant wheat was evaluated using (1) 6846 genome-wide SNP markers that were common between all four data sets, (2)
the set of 12 markers identified in the present GWAS based on transformed means across environments, and (3) the two associated markers that were also significant in the three validation panels. Two of the 12 markers (\textit{Ra_c6266_136} and \textit{GENE-4167_145}) were excluded from all fixed effect matrices to avoid collinearity resulting from linkage. Five-fold cross-validation of ordinary least squares (OLS) and GBLUP models within the GWAS panel confirmed the association between the remaining ten markers and \textit{Pst} resistance, whereas a reduced model with only \textit{RAC875_c1226_652} and \textit{Tdurum_contig29607_413} as predictors resulted in a lower predictive ability (Table 5). In this population, the highest predictive ability was achieved using a GBLUP model with all ten detected markers included as fixed effects. Predicting breeding values in three independent validation panels showed that OLS and GBLUP including the QTL-linked markers as covariates outperformed the standard GBLUP model. Contrary to the cross-validation within the GWAS data set, the estimated breeding values of the three validation panels were more accurate with only \textit{RAC875_c1226_652} and \textit{Tdurum_contig29607_413} as fixed effects compared to models including all ten associated markers as predictors. In these independent data sets, the highest predictive ability was achieved using either OLS or GBLUP treating the two above-mentioned markers as fixed effects. With these models, we could increase predictive ability in the three populations by 0.13–0.46 compared to the standard GBLUP approach.

**Discussion**

Host plant resistance is generally the most ecological and economic strategy for stripe rust disease control. Integration of additional resistance alleles into the genetic background of already resistant cultivars is important for improving the durability of stripe rust resistance in wheat breeding. Understanding the genetic basis of stripe rust resistance could facilitate the transfer of existing or new resistance alleles into high-yielding and regionally adapted bread wheat lines.
In the present study, the frequency distribution of the percentage of disease severity assessed in the field trials was right skewed with a large proportion of resistant lines (Fig. S1A), suggesting that many effective APR and possibly race-nonspecific alleles may be present in this panel. Similar results were obtained when the disease severity of stripe rust was assessed in a European winter wheat diversity panel of 158 old and new wheat cultivars (Miedaner et al. 2020) and in 419 pre-breeding lines developed at CIMMYT (Ledesma-Ramírez et al. 2019). All these studies indicated that this type of resistance is of high priority in breeding programs: it is established through the targeted crossing of resistant lines followed by high selection pressure in early generations. In addition, the broad-sense heritability coefficient ($h^2 = 0.87$) obtained in this study suggests that phenotypic variation in stripe rust severity was mainly due to genotypic effects. High broad-sense heritability values have been reported in previous studies by Ling et al. (2012), Beukert et al. (2020a), and Abou-Zeid and Mourad (2021).

GWAS identified 67 QTL for stripe rust resistance in a panel of 230 winter wheat cultivars and breeding lines. Among all marker loci identified in five environments, only eight SNPs were found significant in at least two environments, therefore could be considered as stable QTL. Four SNPs were found significantly associated with stripe rust resistance for means across environments, but not in individual environments. Among these, two QTL appeared particularly attractive for stripe rust resistance breeding, namely those predicted by markers RAC875_c1226_652 (chromosome 2B) and Tdurum_contig29607_413 (chromosome 6A). Lines in the validation populations combining the favorable alleles at these loci displayed a near immune phenotype.

The results of the present study revealed QTL close to the genomic regions of the stripe rust resistance genes Yr5/YrSP (Macer 1966; Murphy et al. 2009; Feng et al. 2015) and Yr44 (Sui et al. 2009) on chromosome 2B, Yr62 (Lu et al. 2014) on chromosome 4B, and Yr18 (Singh 1992) on chromosome 7D near the SNP markers IAAV1743, AX-94684920, and AX-94720261, respectively. Yr5 provides a high level of resistance to stripe rust and originates from spring spelt Triticum spelta var. album (Macer 1966). It is allelic to YrSP and paralogous to Yr7, both of which have been overcome by several Pst isolates. A QTL (qYr.A) in the same genomic region was previously reported by Losert et al. (2017) in a diverse set of 919 triticale genotypes from the private and public breeding sectors in Europe. In this region, five QTL controlling stripe rust resistance (Table S6) have been reported in common wheat (Guo et al. 2008; Jighly et al. 2015; Ando et al. 2018; Ren et al. 2012; Tehseen et al. 2021).

We found a QTL on chromosome 4B in the region of the Yr62 gene. Lu et al. (2014) found a QTL on chromosome 4BL (QYrPI192252.wgp-4BL) in a mapping population of 150 F$_2$ recombinant inbred lines (derived from a cross between PI 192252 and “Avocet susceptible”) which explained 40–60% of the total phenotypic variation of the relative area under the stripe rust disease progress curve and was inherited as a single gene. The gene, named Yr62, provides a high level of HTAP resistance and was located proximal to Yr50, transferred from T. intermedium into wheat. Jia et al. (2020) and Naruoaka et al. (2015) also reported two QTL for stripe resistance in a similar region on chromosome 4BL.

We discovered a QTL in the Lr34/Yr18 region on chromosome 7DS. Cloning of Lr34/Yr18 has shown that the gene encodes an adenosine triphosphate-binding cassette transporter that resembles a pleiotropic drug resistance transporter (Krattinger et al. 2009). Lr34/Yr18 is active at the adult plant stage and shows moderate but durable resistance to stripe and leaf rust (Spielmeyer et al. 2005). It appears that the gene is relatively common in German cultivars (Zetzsche et al. 2020). However, further investigations are needed to confirm whether the QTL identified in the present study on chromosomes 2BL, 4BL, and 7DS are allelic to or distinct from Yr5/YrSP, Yr44, Yr62, and Yr18, respectively.

Our study also detected four loci associated with stripe rust resistance on chromosomes 2BS, 6AL, 7AL, and 7BL (Table 4), which could correspond to QTL previously reported by Prins et al. (2011), Vazquez et al. (2012), Rosewarne et al. (2012), Agenbag et al. (2014), Miedaner et al. (2019), Beukert et al. (2020a), Jia et al. (2020), and Rollar et al. (2021). Of these, QTL on chromosomes 2BS and 6AL were identified in German plant materials including a winter wheat diversity panel (Miedaner et al. 2019), a hybrid wheat panel (Beukert et al. 2020a), and a multiparental population (Rollar et al. 2021). Interestingly, these two QTL were not reported in the worldwide collections of hexaploid spring (Maccarelli et al. 2015) and winter wheat (Bulli et al. 2016), suggesting that they were specifically enriched through European breeding activities.

On chromosome 2B, the putative QTL associated with RAC875_c1226_652 was in a region that referred to BST_chr2B_nlr_143 and disease resistance protein RGA4. In this region, a QTL (QYr.sgi-2B.1) was previously mapped by Agenbag et al. (2014) near the marker IWB52095, located at 157.694 Mbp of the wheat physical map (IWGSC Refseq v1.1). More recently, the QTL was cloned in bread wheat as a major factor for the race-specific disease resistance gene Yr27, which encodes an intracellular immune receptor (Athiyannan et al. 2022). Yr27 is allelic to leaf rust resistance gene Lr13 with 97% sequence identity. The predicted coding sequence of the gene with a length of 3219 base pairs encodes a protein of 1072 amino acids with an N-terminal coiled-coil domain, a central NB-ARC domain, and a carboxy-terminal leucine-rich repeat (LRR) domain (Athiyannan et al. 2022). In rice, resistance to Magnaporthe oryzae is mediated by
a pair of interacting nucleotide-binding site leucine-rich repeat domain-containing immune sensors, RGA4 and RGA5 (Césari et al. 2014). RGA4 mediates cell death but is repressed by RGA5. The repressor is neutralized by binding pathogen-derived proteins to the dimer. RGA4 and RGA5 interact through their CC domains to form homo- and heterocomplexes. In addition, BLAST searches using the sequence of another SNP marker on chromosome 6AL (Tdurum_contig29607_413) yielded direct hits for a gene annotated as E3 ubiquitin ligase protein, which is a module that controls innate immunity and programmed cell death in plants and strongly contributes to promoting antimicrobial defense while preventing autoimmunity (You et al. 2016). However, the mechanisms contributing to this immune homeostasis are poorly understood. Understanding the mode of action between candidate genes and their effects on disease resistance can help in the development of functional and predictive markers to detect resistant. It also provides new insights into the genetic mechanisms controlling stripe rust resistance in wheat and lays the foundation for characterization, cloning, and manipulation of genes in future studies. Since most of the genes/ QTL identified in this study are already present in adapted varieties and/or elite breeding lines, pyramiding of these genes for breeding new resistant varieties seems relatively straightforward.

The markers identified in the present study showed great potential to facilitate an efficient selection for Pst resistance. OLS and GBLUP models that included RAC875_c1226_652 and Tdurum_contig29607_413 as fixed effects allowed a more accurate prediction of breeding values in the three independent panels compared to a GBLUP model with only the intercept as fixed effect. More complex models with all ten QTL-linked markers as fixed effects were only superior within the GWAS panel but yielded comparably low predictive abilities in the independent validation panels, which can be explained by overfitting. The value of preselected markers for the prediction of Pst resistance was evaluated in previous studies, but the comparison with genome-wide markers did not yield consistent results (Juliana et al. 2017; Muleta et al. 2017; Beukert et al. 2020b). These differing outcomes could be attributed to the size and composition of the training set, the genetic architecture of Pst resistance in the analyzed populations, and the prevalent pathotypes. Nevertheless, the present study demonstrates that, for the Northern and Central European winter wheat gene pool and current pathogen races, the validated QTL on chromosomes 2B and 6A and associated markers appear highly attractive to facilitate selection of Pst resistant cultivars. Since GBLUP with fixed effects for RAC875_c1226_652 and Tdurum_contig29607_413 was superior to OLS, we recommend including these markers in GS models to enrich quantitative, minor-effect alleles for a more sustainable resistance in combination with large-effect alleles.

Overall, our study identified resistant genotypes and the potential source of effective resistance alleles and associated QTL that could be used to improve stripe rust resistance levels in the current Northern and Central European breeding materials, particularly through genomic approaches.

Supplementary Information The online version contains supplementary material available at https://doi.org/10.1007/s00122-022-04202-z.

Acknowledgments We are grateful to our project partners at Saatzucht Josef Breun GmbH & Co. KG for their valuable cooperation and conducting field trials in Lenglern, Germany and Dr. Theresa Albrecht for her preliminary works in selection of the genotypes. Excellent technical assistant of Sabine Schmidt, Kerstin Hoffmann and Petra Greim at LfL is appreciated. We also appreciate Jörg Plieske and Martin Ganal of TraitGenetics for providing unpublished assignments of the 25 k SNP markers to physical positions. JIS was supported by the Beatriz Galindo Program (BEAGAL/18/00115) from the Ministerio de Educación y Formación Profesional of Spain and the Severo Ochoa Program for Centres of Excellence in R&D from the Agencia Estatal de Investigación of Spain, grant SEV-2016-0672 (2017–2021) to the CBGP.

Author Contribution statement FS analyzed the phenotypic data and constructed the molecular map. FS and MG performed genetic analyses and wrote the manuscript. FSch, SR, JH, HK, MS, FL, LM, and HB conducted experimental field trials for phenotyping of stripe rust resistance. VM supported genetic analyses and designing of the project. JIS and DA designed the diversity panel. HB, JIS, ML, and LH conceived the project and obtained fundings. All authors read, edited, and approved the final manuscript.

Funding Open Access funding enabled and organized by Projekt DEAL. Results have been achieved within the framework of the project “WheatSustain” under the ERA-NET Cofund SusCrop (Grant No. 771134), being part of the Joint Programming Initiative on Agriculture, Food Security and Climate Change (FACCE-JPI). This project has received funding from the European Union’s Horizon 2020 research and innovation program under Grant Agreement No. 771134 and with funding from the Research Council of Norway (NFR Grant 299615), Deutsches Bundesministerium für Bildung und Forschung (031B0810), and Bundesministerium für Nachhaltigkeit und Tourismus Österreich (Forschungsprojekt Nr. 101402).

Data availability All datasets generated for this study are included in the article/Supplementary Material.
