Frustrated transition metal compounds in which spin-orbit coupling (SOC) and electron correlation work together have attracted much attention recently. In the case of 5d transition metals, where SOC is large, \( j_{\text{eff}} = 1/2 \) bands near the Fermi level are thought to encompass the essential physics of the material, potentially leading to a concrete realization of exotic magnetic phases such as the Kitaev spin liquid. Here we derive a spin model on a triangular lattice based on \( j_{\text{eff}} = 1/2 \) pseudo-spins that interact via antiferromagnetic Heisenberg (\( J \)) and Kitaev (\( K \)) exchanges, and crucially, an anisotropic (\( \Gamma \)) exchange. Our classical analysis of the spin model reveals that, in addition to small regions of 120\( ^\circ \), \( Z_2 / \text{dual-}Z_2 \) vortex crystal and nematic phases, the stripy and ferromagnetic phases dominate the \( J-K-\Gamma \) phase diagram. We apply our model to the 5d transition metal compound, \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \), in which the \( \text{Ir}^{4+} \) ions form layered two-dimensional triangular lattices. We compute the band structure and nearest-neighbor hopping parameters using \textit{ab-initio} calculations. By combining our \textit{ab-initio} and classical analyses, we predict that \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \) has a stripy ordered magnetic ground state.

I. INTRODUCTION

Transition-metal compounds in which electrons occupy \( d \)-orbitals have proven to be a vast playground for exotic and interesting physics. The non-trivial combination of lattice geometry, crystal field strength, spin-orbit coupling (SOC) and Coulomb repulsion between electrons in transition metals can conspire to produce novel ground states, including a plethora of magnetic orders.\(^{19–26} \)

Recently, a general model of the layered honeycomb iridates was derived in which \( j_{\text{eff}} = 1/2 \) states near the Fermi level captured the essential physics.\(^{28} \) Arising from a combination of strong SOC and the octahedral crystal field environment for each \( \text{Ir}^{4+} \) ion, these \( j_{\text{eff}} = 1/2 \) states effectively behave as spin-1\( /2 \) pseudo-spins. It was found that a variety of magnetic ground states could be realized depending on the competition between Heisenberg (\( J \)), Kitaev (\( K \)) and symmetric off-diagonal (\( \Gamma \)) spin exchanges at the nearest-neighbor level. The general principles applied to the honeycomb iridates can also be turned to triangular iridates which can harbor similar spin anisotropy.

Spins on a triangular lattice are inherently frustrated - potentially leading to new magnetic phases. It is therefore important to study the interaction between \( j_{\text{eff}} = 1/2 \) pseudo-spins on a triangular lattice which have a microscopic origin similar to that in the honeycomb iridates. Classical and quantum studies of the Heisenberg-Kitaev (HK) model have been performed on the triangular lattice,\(^{29,30} \) with possible applications to the triangular iridate \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \).\(^{31} \) It has been shown that the HK model hosts an interesting \( Z_2 \) vortex crystal phase which could be realized in \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \); moreover, the presence of the Kitaev exchange destabilizes the 120\( ^\circ \) ordered phase of the Heisenberg model on the triangular lattice. We will argue, however, that this model is incomplete and does not describe the physics of \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \); a more comprehensive approach is required.

![FIG. 1. (Color online) (a) The major nearest-neighbor hopping channels in the limit of ideal octahedra. The parameters \( t_1 \) and \( t_2 \) describe two distinct \( d \)-orbital overlaps, while \( t_2 \) includes both \( d \)-orbital overlap and oxygen mediated hoppings. The green, blue and red dotted lines label the \( z \), \( y \) and \( z \) bond types according to the convention \( \alpha \beta (\gamma) \) in Eq. (1).](image)

In this paper, we derive a spin model that is generic to layered triangular iridate compounds such as \( \text{Ba}_3\text{IrTi}_2\text{O}_9 \). Our derivation is founded upon the reasonable assumption that electron interaction strength (\( U \)) and Hund’s coupling (\( J_H \)) provide the largest energy scales in the system, with SOC being the next largest...
energy scale, and electron hopping between \( d \)-orbitals as the smallest energy scale. In addition, we assume that the symmetries of an ideal triangular lattice of octahedra are respected in our derivation. From this foundation we derive a nearest-neighbor spin model with three spin exchanges: Heisenberg \( (J) \), Kitaev \( (K) \) and a symmetric off-diagonal exchange \( (\Gamma) \). We map out the classical magnetic ground state phase diagram through a combination of Luttinger-Tisza and classical Monte Carlo techniques and discuss its intricacies.

We next apply our general model to the triangular iridate \( \text{Ba}_3\text{Ir}_2\text{O}_9 \) by first performing \textit{ab-initio} calculations to determine its band structure with and without SOC. We then demonstrate that the states near the Fermi level are well described by \( j_{\text{eff}} = 1/2 \) states, and we further estimate the nearest-neighbor tight-binding parameters. Consequently, we can estimate the region of the phase diagram that pertains to \( \text{Ba}_3\text{Ir}_2\text{O}_9 \) (with and without the effects of octahedral distortion) and predict that it should exhibit striply magnetic order in its ground state. Finally, experimental methods to test our predictions are also discussed.

Our paper is organized in the following manner. We derive our general \( j_{\text{eff}} = 1/2 \) spin model on a triangular lattice and analyze its classical phase diagram in Section II. In Section III we discuss the crystal structure of \( \text{Ba}_3\text{Ir}_2\text{O}_9 \), present the results of our \textit{ab-initio} calculations, estimate the strengths of the spin exchanges from \textit{ab-initio} tight-binding parameters, and predict the ground state for \( \text{Ba}_3\text{Ir}_2\text{O}_9 \) using our model. In Section IV we examine the effects of octahedral distortion in \( \text{Ba}_3\text{Ir}_2\text{O}_9 \) within our spin model. Finally, in Section V, we discuss and summarize the ramifications of these results and suggest possible experimental tests.

II. DERIVATION OF \( j_{\text{eff}}=1/2 \) SPIN MODEL ON A TRIANGULAR LATTICE & LUTTINGER-TISZA AND CLASSICAL MONTE CARLO ANALYSIS

We begin by constructing a model of a triangular lattice of isolated \( \text{Ir}^{4+} \) ions which are surrounded by ideal oxygen octahedra as in Fig. 1. The local octahedral crystal field will split the \( \text{Ir}^{4+} 5d \) levels into \( t_{2g} \) and \( e_g \) states. The large SOC of the \( \text{Ir}^{4+} \) ions will further split the \( t_{2g} \) manifold into completely filled \( j_{\text{eff}} = 3/2 \) states and half-filled \( j_{\text{eff}} = 1/2 \) states. Since the strong on-site Coulomb interactions localize these \( j_{\text{eff}} = 1/2 \) states, we can then consider the effective physics to be captured by interacting \( j_{\text{eff}} = 1/2 \) pseudo-spins. To arrive at this picture concretely, we start from a microscopic Hamiltonian which includes nearest-neighbor \( d \)-orbital hoppings as perturbations on top of an on-site Kanamori Hamiltonian (see the Supplementary Material for more details). There are two types of \( d \)-orbital hopping at the nearest-neighbor level as shown in Fig. 1: direct overlap between \( d \)-orbitals on \( \text{Ir}^{4+} \) sites (denoted by \( t_1 \) and \( t_3 \)), and oxygen mediated hopping via \( p \)-orbitals (denoted by \( t_2 \)).

The nearest-neighbor spin model takes the form

\[
H = \sum_{\alpha\beta(\gamma) \in \langle ij \rangle} \left[ J S_i^\alpha \cdot S_j^\beta + K S_i^\gamma S_j^\gamma + \Gamma (S_i^\alpha S_j^\beta S_i^\gamma S_j^\gamma + S_i^\alpha S_i^\gamma S_j^\beta S_j^\gamma + S_i^\beta S_i^\gamma S_j^\alpha S_j^\gamma) \right],
\]

where \( i, j \) denote \( \text{Ir}^{4+} \) sites, and \( S_i \) is a \( j_{\text{eff}} = 1/2 \) spin operator at a site with components \( S_i^\alpha \) \((\alpha = x, y, z)\). The exchanges \( J \) and \( K \) are Heisenberg and Kitaev exchanges respectively, while \( \Gamma \) is a symmetric off-diagonal exchange (exact expressions can be found in the Appendix). We identify each bond as one of either \( yz(x), zx(y) \) or \( xy(z) \) bonds, labeled by \( \alpha\beta\gamma \). The spin components that interact on each bond depend on the bond type \( \alpha\beta\gamma \).

We studied the phase space of the spin model using a combination of Luttinger-Tisza (LT) and classical Monte Carlo (CMC) analyses in order to determine the ground state for varying exchange parameters. We employed the simulated annealing technique in our CMC calculations, whereby the transition probability from state to state is determined by a temperature parameter that is slowly lowered until there is no improvement in the ground state energy. The classical approaches are considered simultaneously in Fig. 2. The LT and CMC analyses were found to agree with each other in both energy and spin configuration, except for small regions of the phase diagram computed by CMC (bounded by the dotted line toward the boundary), where LT could not identify the exact classical ground state. The exchanges are parameterized in spherical coordinates such that \( J = \sin \theta \cos \phi \), \( K = \sin \theta \sin \phi \) and \( \Gamma = \cos \theta \) where \( \theta \in [0, \pi] \), and \( \phi \in [0, 2\pi] \). The Heisenberg-Kitaev (HK) model is recovered in the limit in which \( \theta = \pi/2 \), where \( \Gamma = 0 \). We find six different magnetic orderings: ferromagnet (FM), stripy (ST), 120° order (120), nematic (N), \( Z_2 \) vortex crystal and dual-\( Z_2 \) vortex crystal. We depict the FM, ST, and 120 orders in the insets of Fig. 2 while nematic, \( Z_2 \) vortex crystal and dual-\( Z_2 \) vortex crystal phases are depicted in the Supplementary Material. A thorough description of \( Z_2 \) and dual-\( Z_2 \) orders can be found in Refs. 29 and 30.

The boundaries of both phase diagrams in Fig. 2 coincide, and show the classical ground states of the HK model (\( \Gamma = 0 \) in Eq. 1)). We first highlight some special points. The Heisenberg model (\( J = 1 \)) hosts 120° order, agreeing with the known ground state on a triangular lattice. We also find that perturbing away from the Heisenberg model by adding \( K \) tends to destabilize 120° order toward the previously discussed \( Z_2 \) vortex crystal phase. The \( K = 1 \) point represents the Kitaev model on the triangular lattice. Here we find that the spins tend to order antiferromagnetically in chains along one of the three principal directions of the triangular lattice, with each chain decoupled from the rest. By flipping all the spins in any of the chains, the energy remains the same and so this state is highly degenerate - exponential in the size of the system. This classical ground state degeneracy has
Recently, it has been analyzed and shown to be lifted by quantum fluctuations through an order-by-disorder mechanism, introducing a coupling between spins of next-nearest neighboring antiferromagnetic chains. Overall, the boundary of the phase diagram is in agreement with the previous Monte Carlo studies of the HK model on the triangular lattice.

However, when adding $\Gamma$, whether positive or negative, to the Heisenberg model, we find that 120° order emerges. For positive $\Gamma$, we find that 120° order persists until the degenerate $\Gamma = 1$ point, where 120°, FM and ST orders meet. For the Kitaev model, on the other hand, the introduction of small $|\Gamma|$ immediately gives ST order as the magnetic ground state. The majority of the phase diagram upon the inclusion of $\Gamma$ is dominated by stripy or ferromagnet phases.

III. APPLICATION TO Ba$_3$IrTi$_2$O$_9$

Ba$_3$IrTi$_2$O$_9$ has a layered triangular lattice structure composed of Ir$^{4+}$ ions with a $d^5$ electron configuration surrounded by oxygen octahedra. It belongs to space-group $P6_3mc$, possessing a mirror plane and a screw axis along the $c$-direction, connecting the top and bottom halves of the unit cell. The bottom half of the unit cell is shown bounded by the rectangular box in Fig. 3b. The IrO$_2$ layers are separated by two TiO$_2$ layers, with the Ir$^{4+}$ ions face-sharing their octahedra with the Ti$^{4+}$ octahedra directly above them along the $c$-axis. The Ba$^{2+}$ ions populate the unit cell among the IrO$_2$ and TiO$_2$ layers. There are two Ir$^{4+}$ ions belonging to the primitive unit cell, each of which belongs to different IrO$_2$ layers that form a triangular lattice, shown in Fig. 3b. The distortion of the local octahedra, depicted in Fig. 3c, is discussed in the next section.

The local environment for the electrons at each site, with an octahedral crystal field, and large SOC, is reminiscent of that in Na$_2$IrO$_3$, Li$_2$IrO$_3$ and α-RuCl$_3$. Therefore, we may expect that Ba$_3$IrTi$_2$O$_9$ can be described by similar physical principles involving pseudo-spin $j_{\text{eff}} = 1/2$ states near the Fermi level. Unlike in honeycomb iridates, however, Ba$_3$IrTi$_2$O$_9$ forms triangular lattice layers and the oxygen octahedra surrounding the Ir$^{4+}$ ions are not edge-shared. Here we explain that the $j_{\text{eff}} = 1/2$ spin model derived in the previous section captures the essential physics of Ba$_3$IrTi$_2$O$_9$. To this end, we perform a series of band structure calculations for Ba$_3$IrTi$_2$O$_9$ and determine the nature of the electronic states near the Fermi level.

We used OpenMX, which implements the linear-combination-of-pseudo-atomic-orbitals method, to compute the band structure of Ba$_3$IrTi$_2$O$_9$ with and without SOC. A non-collinear DFT scheme and a fully relativistic $j$-dependent pseudopotential are used to treat SOC, with the Perdew-Zunger parameterization of the local density approximation (LDA) chosen for the exchange-correlation functional. We chose an energy cutoff of 300 Ry for the real-space sampling and used an $8 \times 8 \times 3$ $k$-grid for the Brillouin zone sampling. We used the maximally-localized Wannier orbitals method implemented in OpenMX to obtain the tight-binding Hamil-
connected by the black double-arrowed line. The Ir
4+ neighbor Ir atoms belonging to different unit cells are con-

totonic for Ir t2g orbitals.

The results of our calculation are shown in Fig 4. The
calculated band structure without SOC is shown in Fig
4a alongside the projected density of states (PDOS). The
bands near the Fermi level are composed of p-orbitals from oxygen and t2g orbitals coming from the Ir
4+ ions. A gap of approximately 1 eV separates these bands from
the empty Ti d-bands. We note that the bandwidth is
relatively small, reflecting the large distance between Ir
4+ sites.

To understand the effects of SOC, we also computed
the band structure including SOC, shown in Fig 4b with
the bands and PDOS projected onto the \( j_{\text{eff}} = 1/2 \) and
3/2 states. We find that the t2g bands are split by SOC
into well-separated \( j_{\text{eff}} = 1/2 \) (pink) and \( j_{\text{eff}} = 3/2 \) (teal)
states. The five valence electrons will serve to completely
fill the \( j_{\text{eff}} = 3/2 \) states and half-fill the \( j_{\text{eff}} = 1/2 \) states. We can therefore expect the effective physics
of Ba3IrTi2O9 to be well described by the pseudo-spin
\( j_{\text{eff}} = 1/2 \) model derived in the previous section.

Having established the \( j_{\text{eff}} = 1/2 \) nature of
Ba3IrTi2O9, we can further estimate the hopping parameters coming from the major hopping channels depicted schematically in Fig 4. We again use the maxially-
localized Wannier orbital method to estimate the nearest-
neighbor hopping parameters. In the limit of ideal local
crystal, we find that the nearest-neighbor hopping parameters are \( t_1 = 7.4 \text{ meV} \), \( t_2 = -23.5 \text{ meV} \)
and \( t_3 = -119 \text{ meV} \). All further neighbor hopping parameters are found to be small (\( \lesssim 5 \text{ meV} \)), therefore, a tight
binding model including only nearest-neighbor parameters will aptly describe the kinetic microscopics.

From our ab-initio calculations, we can estimate the strength of the exchanges knowing the strengths of the
nearest-neighbor tight binding parameters. Taking onsite Coulomb repulsion to be \( U = 2.0 \text{ eV} \) and fixing the ratio of Hund's coupling to \( U \) as \( J_H/U = 0.2 \), we
find \( J \approx 2 \text{ meV}, K \approx 4 \text{ meV} \) and \( \Gamma \approx -2 \text{ meV} \) for Ba3IrTi2O9. Normalizing the exchange couplings
by \( N = \sqrt{J^2 + K^2 + \Gamma^2} \) (so that \( J^2 + K^2 + \Gamma^2 = 1 \)),
we equivalently find \( J/N \approx 0.36, K/N \approx 0.86 \) and \( \Gamma/N = -0.36 \), with the Kitaev exchange being the domi-
nant exchange at the nearest-neighbor level. We also
point out that \( \Gamma \) is non-zero and negative. This area of
phase space is marked by the white star in Fig. 2, and
falls into the striped region of magnetic order.

Our analysis has been performed under the most gen-
eral considerations imposed by the symmetries of the lat-
tice and the local electron environment at each site, ar-
riving at the model in Eq. (1). When \( \Gamma = 0 \), our model
reduces to the HK model; however, the HK model is ins-
sufficient to describe Ba3IrTi2O9 as seen in the significant
\( \Gamma \) that is of the same strength as the Heisenberg exchange
\( J \). Indeed, even a relatively small \( \Gamma \) can act to unsettle
the phases on the boundary of the phase diagram. More-
over, all layered triangular systems of this kind can be
treated with our model and, barring fine-tuning of the
tight binding parameters, \( \Gamma \) is not zero in general.

IV. EFFECTS OF OCTAHEDRAL DISTORTION

We also investigated the presence of the distortion in the oxygen octahedra, which breaks inversion symmetry
about the Ir-Ir bond center. Such a distortion will induce
two inequivalent oxygen mediated hoppings, \( t_2 \) and \( t_2' \)
shown in Fig. 3b, as well as other potential hoppings.
From our ab-initio calculations, we estimate that \( t_2 = -13 \text{ meV} \) and \( t_2' = -32 \text{ meV} \). In the case of Ba3IrTi2O9,
we only consider these hopping parameters since our ab-
initio calculations suggest that other hopping channels
created by the distortion have small amplitudes (less than
half of \( t_2 \)).
magnetic ground state near the Kitaev limit. Our prediction for stripy order as the magnetic ground state of Ba$_3$IrTi$_2$O$_9$ can be verified by neutron scattering. A magnetic peak at ordering wave vector M in the Brillouin zone would correspond to stripy order according to our analysis.

A previous experimental study of Ba$_3$IrTi$_2$O$_9$ measured zero-field-cooled and field-cooled magnetic susceptibility in the temperature range of 2-400 K, as well as heat capacity measurements from 0.35-295 K. No long range magnetic ordering was reported in this experimental study; however, X-ray powder diffraction of Ba$_3$IrTi$_2$O$_9$ at room temperature revealed large site sharing between Ir$^{4+}$ and Ti$^{4+}$ ions of (37 ± 10)%. It is possible that the site sharing between Ir$^{4+}$ and Ti$^{4+}$ ions could lead to a nonmagnetic dilution of the triangular layers. Studies of nonmagnetic dilution have been recently undertaken on the honeycomb iridates AIrO$_3$ (A = Li, Na) with the observation of possible spin-glass behavior. Further studies of nonmagnetic dilution on triangular lattices, which may enhance frustration and induce a correlated paramagnetic phase, can be important both in understanding material properties and in real-

V. DISCUSSION AND CONCLUSION

In summary, we have derived a general $j_{\text{eff}} = 1/2$ spin model on a triangular lattice based on lattice symmetry considerations and the interplay between strong electron correlations, large SOC and a local octahedral crystal field environment. By employing Luttinger-Tisza and classical Monte Carlo, we have identified six distinct magnetic ground states supported by our model. We then determined the electronic band structure and nature of the states near the Fermi level in the layered triangular compound Ba$_3$IrTi$_2$O$_9$ from ab-initio calculations, and found that it is well described by the pseudo-spin $j_{\text{eff}} = 1/2$ picture. Applying our ab-initio calculations to our general spin model, we predict that Ba$_3$IrTi$_2$O$_9$ hosts a stripy magnetic ground state near the Kitaev limit. Our prediction for stripy order as the magnetic ground state of Ba$_3$IrTi$_2$O$_9$ can be verified by neutron scattering. A magnetic peak at ordering wave vector M in the Brillouin zone would correspond to stripy order according to our analysis.

A previous experimental study of Ba$_3$IrTi$_2$O$_9$ measured zero-field-cooled and field-cooled magnetic susceptibility in the temperature range of 2-400 K, as well as heat capacity measurements from 0.35-295 K. No long range magnetic ordering was reported in this experimental study; however, X-ray powder diffraction of Ba$_3$IrTi$_2$O$_9$ at room temperature revealed large site sharing between Ir$^{4+}$ and Ti$^{4+}$ ions of (37 ± 10)%. It is possible that the site sharing between Ir$^{4+}$ and Ti$^{4+}$ ions could lead to a nonmagnetic dilution of the triangular layers. Studies of nonmagnetic dilution have been recently undertaken on the honeycomb iridates AIrO$_3$ (A = Li, Na) with the observation of possible spin-glass behavior. Further studies of nonmagnetic dilution on triangular lattices, which may enhance frustration and induce a correlated paramagnetic phase, can be important both in understanding material properties and in real-

**Appendix A: Derivation of \( j_{\text{eff}} = 1/2 \) spin model without octahedra distortion**

We derive the spin model in the limit of ideal octahedra by performing a strong coupling expansion in the limit where \( U, J_H \gg \lambda_{SO} \gg t \), with \( U \) being the strength of the Coulomb interaction, \( J_H \) is Hund’s coupling, \( \lambda_{SO} \) is the SOC strength and \( t \) are the tight binding parameters. We start by considering an on-site Kanamori Hamiltonian,

\[
H_0 = \sum_i \left( \frac{U}{2} (N_i - 5)^2 - 2J_HS_i^z - \frac{J_H}{2} L_i^z \right),
\]

(A1)

where \( i \) denotes the \( 1^{4+} \) site index, and \( N_i, S_i \) and \( L_i \) are the total number, spin and angular momentum operator on the \( i \)th site.

To derive an effective spin Hamiltonian, we consider electron hopping through major nearest-neighbor \( d \)-orbital hopping channels as small perturbations on top of \( H_0 \) within the framework of second order perturbation theory. The kinetic part of the Hamiltonian (along a \( z \)-bond for instance) takes the general form

\[
T_{ij}^z + (T_{ij}^z)^\dagger = \sum_{\sigma,\alpha,\beta} \left( d_{i\alpha\sigma}^\dagger \tilde{T}^z_{\alpha\beta} d_{j\beta\sigma} + d_{j\beta\sigma}^\dagger (\tilde{T}^z)^\dagger_{\alpha\beta} d_{i\alpha\sigma} \right),
\]

where \( d_{i\alpha\sigma}^\dagger \) creates a \( d \)-orbital electron \((\alpha, \beta = yz, zx, xy)\) on site \( i \) with spin \( \sigma \), and \( \tilde{T}^z \) is the hopping matrix along the \( z \)-bond connecting the orbitals on the two nearest-neighbor sites. In the ideal octahedra limit, the hopping matrix is restricted by \( C_2 \) rotation symmetry along the bond connecting the two sites and \( C_{2z} \) symmetry about the bond center to the form (in the \( |yz\rangle, |zx\rangle, |xy\rangle \) basis):

\[
\tilde{T}^z = \begin{pmatrix}
t_1 & t_2 & 0 \\
t_2 & t_1 & 0 \\
0 & 0 & t_3
\end{pmatrix}.
\]

(A2)

The resulting perturbed Hamiltonian is projected onto the \( j_{\text{eff}} = 1/2 \) subspace since the SOC is large. In terms of the \( j_{\text{eff}} = 1/2 \) spin operators, we arrive at the effective Hamiltonian

\[
H_{\text{ideal}} = \sum_{\alpha\beta(\gamma) \in (ij)} \left( J S_i^\alpha \cdot S_j^\beta + KS_i^\alpha S_j^\gamma + \Gamma(S_i^\alpha S_j^\beta + S_i^\beta S_j^\alpha) \right),
\]

(A3)

written in the main text, with

\[
J = \frac{4}{27} \left( \frac{6t_1(t_1 + 2t_3)}{U - 3J_H} + \frac{2(t_1 - t_3)^2}{U - J_H} + \frac{(2t_1 + t_3)^2}{U + 2J_H} \right),
\]

(A4)

\[
K = \frac{8J_H}{9} \left( \frac{(t_1 - t_3)^2 - 3t_2^2}{(U - 3J_H)(U - J_H)} \right),
\]

(A5)

\[
\Gamma = \frac{16J_H}{9} \left( \frac{t_2(t_1 - t_3)}{(U - 3J_H)(U - J_H)} \right).
\]

(A6)

**Appendix B: Expression for spin exchanges when including octahedra distortion effects**

As discussed in the main text, the distorted octahedra add two new hopping parameters \( t_2 \) and \( t_3 \). In terms of the hopping matrix of the previous section, we have (in the \( |yz\rangle, |zx\rangle, |xy\rangle \) basis):

\[
\tilde{T}^z_{\text{distorted}} = \begin{pmatrix}
t_1 & t_2 & 0 \\
t_2 & t_1 & 0 \\
0 & 0 & t_3
\end{pmatrix}.
\]

(B1)

This non-symmetric hopping matrix introduces a Dzyaloshinskii-Moriya exchange in the effective Hamiltonian and also splits the Heisenberg and Kitaev exchanges found in the ideal limit. Along a \( z \)-bond (sites 1 and 2), the Hamiltonian takes the form

\[
H_{\text{distorted}} = J_x S_1^x S_2^x + J_y S_1^y S_2^y + J_z S_1^z S_2^z + D(S_1^y S_2^x - S_1^x S_2^y) + \Gamma(S_1^\alpha S_2^\gamma + S_1^\gamma S_2^\alpha),
\]

(B2)

with the new exchange parameters given by,

\[
J_x = \frac{4}{27} \left( \frac{4t_1^2 - 4t_1t_3 - 2t_2^2 + t_2t_3^2 + 2t_3^2}{U - J_H} + \frac{3(2t_1^2 + 4t_1t_3 + t_2t_3^2 - t_3^2)}{(U - 3J_H)(U - 2J_H)} \right),
\]

\[
J_y = \frac{4}{27} \left( \frac{4t_1^2 - 4t_1t_3 + t_2^2 + t_2t_3^2 - 2t_3^2 + 2t_3^2}{U - J_H} + \frac{3(2t_1^2 + 4t_1t_3 - t_3^2 + t_2^2)}{(U - 3J_H)(U - 2J_H)} \right),
\]

\[
J_z = \frac{4}{27} \left( \frac{4t_1^2 - 4t_1t_3 + t_3^2}{U - J_H} + \frac{3(2t_1^2 + 4t_1t_3)}{(U - 3J_H)(U - 2J_H)} \right).
\]
\[ J_z = \frac{4}{27} \left( \frac{-t_1^2 + 2t_1 t_3 + 2t_2 t_3 + 5t_1 t'_2 + 2t_2 t'_2 - t_3^2}{U - J_H} \right) \]
\[ \times \left( \frac{3(-3t_1^2 - 2t_1 t_3 + 3t_2 t'_2 - t_3^2)}{U - 3J_H} + \frac{4t_1^3 + 4t_1 t_3 + t_3^2 - 2t_2 t'_2 + t_2^2 + t_3^2}{U + 2J_H} \right). \]

\[ \Gamma = \frac{8}{9} J_H \left( t_2 + t'_2 \right) \left( t_1 + t_3 - t_2 + t'_2 \right) \]
\[ D = -\frac{8}{27} \left( t_2 - t'_2 \right) \left( 3(t_1 + t_3) - t_1 - t_3 + \frac{t_1 + t_3}{U - 3J_H} + \frac{2t_1 + t_3}{U + 2J_H} \right). \]

For Ba$_3$IrTi$_2$O$_9$, we find the following tight-binding parameters from *ab-initio* calculations: $t_1 = 7.4$ meV, $t_2 = -13$ meV, $t'_2 = -32$ meV and $t_3 = -119$ meV. Taking on-site Coulomb repulsion to be $U = 2.0$ eV and fixing $J_H/U = 0.2$, we find $J^x \simeq 2$ meV, $J^y \simeq 2$ meV, $J^z \simeq 6$ meV, $\Gamma \simeq -2$ meV and $D \simeq 2$ meV. We return to the ideal octahedral limit when $t_2 = t'_2 = -23.5$ meV. In this limit we find $J \simeq 2$ meV, $K \simeq 4$ meV and $\Gamma \simeq -2$ meV.

### Appendix C: Real Space Spin Representation of Phases

Real space spin representations of nematic, $Z_2$ and dual-$Z_2$ phases from CMC are shown in Fig. 3. These phases are found near the boundary of the phase diagrams in Fig. 2, where $\Gamma$ is small. The nematic phase, Fig. 5a, is found near the Kitaev limit, and characterized by uncorrelated antiferromagnetic chains that point along one of the three principal directions of the triangular lattice. The $Z_2$ vortex crystal phase and dual-$Z_2$ vortex crystal phases are shown in Figures 6 and 7 respectively, and are discussed in Refs. 29 and 30. The $Z_2$ vortex crystal phase is incommensurate and features large vortices that span the lattice. It emerges upon perturbation of the Heisenberg model on the triangular lattice with a small Kitaev term. The dual-$Z_2$ vortex crystal phase is related to the $Z_2$ vortex crystal phase via Klein duality - a four-sublattice transformation of the spins that maps $J \rightarrow -J$ and $K \rightarrow 2J + K$.

FIG. 5. (Color online) Real space spin configuration examples of nematic (a), $Z_2$ vortex crystal (b) and dual-$Z_2$ vortex crystal phases. The orientation of each spin into (out of) the triangular plane is represented by the blueness (redness) of the color of the spins. The colored boundary around each phase corresponds to the color used to label the phase in Fig. 2 of the main text.
