ABSTRACT

OBJECTIVES This study sought to develop an integrative positron emission tomography (PET) with magnetic resonance imaging (MRI) procedure for accurate atherosclerotic plaque phenotyping, facilitated by clinically approved and nanobody radiotracers.

BACKGROUND Noninvasive characterization of atherosclerosis remains a challenge in clinical practice. The limitations of current diagnostic methods demonstrate that, in addition to atherosclerotic plaque morphology and composition, disease activity needs to be evaluated.

METHODS We screened 3 nanobody radiotracers targeted to different biomarkers of atherosclerosis progression, namely vascular cell adhesion molecule (VCAM)-1, lectin-like oxidized low-density lipoprotein receptor (LOX)-1, and macrophage mannose receptor (MMR). The nanobodies, initially radiolabeled with copper-64 (64Cu), were extensively evaluated in Apoe–/– mice and atherosclerotic rabbits using a combination of in vivo PET/MRI readouts and ex vivo radioactivity counting, autoradiography, and histological analyses.

RESULTS The 3 nanobody radiotracers accumulated in atherosclerotic plaques and displayed short circulation times due to fast renal clearance. The MMR nanobody was selected for labeling with gallium-68 (68Ga), a short-lived radioisotope with high clinical relevance, and used in an ensuing atherosclerosis progression PET/MRI study. Macrophage burden was longitudinally studied by 68Ga-MMR–PET, plaque burden by T2-weighted MRI, and neovascularization by dynamic contrast-enhanced (DCE) MRI. Additionally, inflammation and microcalcifications were evaluated by fluorine-18 (18F)-labeled fluorodeoxyglucose (18F-FDG) and 18F-sodium fluoride (18F-NaF) PET, respectively. We observed an increase in all the aforementioned measures as disease progressed, and the imaging signatures correlated with histopathological features.

CONCLUSIONS We have evaluated nanobody-based radiotracers in rabbits and developed an integrative PET/MRI protocol that allows noninvasive assessment of different processes relevant to atherosclerosis progression. This approach allows the multiparametric study of atherosclerosis and can aid in early stage anti-atherosclerosis drug trials. (J Am Coll Cardiol Img 2018; –: ––) © 2018 The Authors. therosclerosis is an inflammatory disorder of the major arteries that is causative of cardiovascular disease (1). Lipid-driven progression of inflamed atherosclerotic lesions, initiated by vascular endothelium disruption, causes their development into plaques. In the process, inflammatory monocytes are recruited, which subsequently differentiate into macrophages that proliferate and evolve into foam cells (2,3). Further progression is characterized by calcium deposits and additional lipid accumulation, resulting in plaque expansion with hypoxia-induced neovascularization (4). Eventually, acute cardiovascular events like myocardial infarction and stroke may occur as a result of plaque erosion or rupture. Unfortunately, myocardial infarction and sudden cardiac death are frequently the first signs of cardiovascular disease in patients with otherwise a risk factor-free profile (5).

The limitations of current diagnostic methods demonstrate that, in addition to plaque morphology and composition, disease activity needs to be evaluated (6). Over the past 2 decades, many different imaging approaches have been proposed to study the pathophysiological processes associated with atherosclerosis progression (7). Positron emission tomography (PET) imaging with 18F-labeled fluoroxyglucose (18F-FDG), for instance, is a clinically viable method to noninvasively quantify plaque inflammation (8,9). However, 18F-FDG lacks specificity as it is taken up by metabolically active cells, rendering imaging of the coronary arteries particularly challenging due to avid myocardial uptake (10). More recently, 18F-sodium fluoride (18F-NaF) PET has emerged as a promising method to visualize plaque microcalcifications (11). Yet, due to the inherent limitations of standalone molecular imaging techniques, precise phenotyping of atherosclerotic lesions would profoundly benefit from an integrative multimodal imaging approach allowing simultaneous quantification of different key disease progression features. This would not only have a potential impact on future anti-atherosclerosis drug clinical drug trials (9), but it is immediately relevant on a pre-clinical level, both for a better understanding of atherosclerosis biology and the development and evaluation of new drugs, noninvasively and longitudinally in animals.

The advent of fully integrated PET/magnetic resonance imaging (MRI) scanners brings together the strengths of the individual imaging modalities, that is, MRI’s excellent soft tissue contrast and real 3-dimensional imaging capabilities, and PET’s sensitivity and radiotracer specificity. This synergy can be exploited advantageously for vessel wall imaging, as it allows accurate delineation of lesions and coregistration of functional information derived from the radiotracer’s PET signal. In addition, MRI functional methods can be integrated to assess vessel wall permeability, as a measure of plaque neovascularization (12), and may be combined with vessel wall morphological assessment (13).

Here, we integrated nanobody radiotracer technology in a multiparametric PET/MRI protocol that allows precise characterization of the atherosclerotic plaque. Antibodies have been extensively used as PET/single-photon emission computed tomography radiotracers, although long blood circulation times prohibit their use for vessel wall imaging. In contrast, nanobody-based radiotracers are extremely well suited for this purpose, as their high affinity and specificity are similar to antibodies (14), but their markedly smaller size facilitates rapid blood clearance (Figure 1A). Capitalizing on established work (15–17), we selected 3 nanobodies specific to different clinically relevant key markers of atherosclerosis...
progression (18), namely vascular cell adhesion molecule (VCAM)-1 (19), lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1) (20), and macrophage mannose receptor (MMR) (21) (Figure 1B). These nanobodies, labeled with copper-64 (64Cu), were first extensively screened in Apoe−/− mice and atherosclerotic rabbits (Figure 1C). Finally, the MMR nanobody was further developed into a gallium-68 (68Ga)-labeled PET tracer. This tracer was then integrated in a multimodal protocol on a clinical PET/MRI system to simultaneously study vessel wall morphology and atherosclerotic plaque activity. The imaging protocol, involving 68Ga-MMR nanobody-PET, anatomical and dynamic contrast
enhanced (DCE) MRI, in addition to $^{18}$F-FDG-PET and $^{18}$F-NaF-PET, was applied to study atherosclerosis progression in rabbits (Figure 1C).

**METHODS**

A complete description of the methods is provided in the Online Appendix. All animal experiments were performed in accordance with protocols approved by the Institutional Animal Care and Use Committees of Mount Sinai and/or Memorial Sloan Kettering Cancer Center and followed National Institutes of Health guidelines for animal welfare.

**RESULTS**

**NANOBODY-RADIOTRACER SCREENING IN MICE.** Nanobodies targeting 3 relevant markers of...
Atherosclerosis progression (15–17) were screened for use in molecular imaging of atherosclerosis. A nanobody targeting myeloma protein was used as chemical control. The nanobodies were functionalized with the chelator 1,4,7-triazacyclononane-1,4,7-triacetic acid (NOTA). This modification was well tolerated, as the target affinity was retained (Online Table 1). The nanobodies were radiolabeled with $^{64}$Cu for preliminary in vivo screening in Apoe$^{-/-}$ mice, as this radioisotope allows extensive ex vivo evaluation due to its 12.7-h decay half-life. Radiolabeling of all nanobodies proceeded in high radiochemical yield and purity (Figure 1D). Biodistribution in Apoe$^{-/-}$ mice at 3 h post-injection (p.i.) revealed high kidney uptake for all nanobodies, but with varying organ/tissue distribution patterns (Figure 2A, Online Table 2). Moreover, all nanobodies showed rapid blood radioactivity clearance with blood half-lives shorter than 2 min (Online Figure 1). Autoradiography revealed preferential $^{64}$Cu deposition at typical lesion sites such as the aortic root for all radiotracers, whereas the control nanobody showed a homogeneous distribution pattern (Figure 2B). Whole-aorta radioactivity concentration was highest for $^{64}$Cu-MMR, as was the aorta-to-blood ratio (Figure 2C). We selected $^{64}$Cu-MMR and $^{64}$Cu-VCAM for additional micro-PET/computed tomography imaging, showing significant radioactivity accumulation in the aortic root and arch, where advanced lesions typically develop (Figure 2D). Strong kidney and bladder signals were observed, indicative of fast renal clearance. Radiotracer cellular specificity in the plaque was assessed in sections taken from the aortic root of mice injected with the radiolabeled nanobodies. Autoradiography of aortic sections showed colocalization of radioactivity with the expected cell types for each nanobody, that is, endothelial cells for $^{64}$Cu-VCAM, macrophages for $^{64}$Cu-MMR, and both for $^{64}$Cu-LOX, and immunofluorescence confirmed target specificity for all nanobodies (15-17) (Figure 2E).

**PET/MRI Plaque Phenotyping of Rabbit Atherosclerotic Aortas.** In vivo imaging experiments were conducted for the 3 $^{64}$Cu-labeled nanobodies in a rabbit model of atherosclerosis using a clinical PET/MRI scanner (Online Figure 2). A comprehensive in vivo PET/MRI analysis of

TABLE 1 Key Features of the 64Cu-Nanobody Tracers Described in This Study

|          | 64Cu-VCAM | 64Cu-MMR | 64Cu-LOX |
|----------|-----------|----------|----------|
| Target   | VCAM-1 (19)| MMR (21) | LOX-1 (20) |
| Expressed on | Endothelial cells | Macrophages | Endothelial cells and macrophages |

Mouse

| Ex vivo | Aorta-to-blood ratio | 1.0 (0.6-1.1) | 3.3 (2.6-4.7) | 1.7 (1.3-3.6) |
|         | Aorta-to-muscle ratio | 7.3 (7.3-10.3) | 3.0 (2.0-9.6) | 2.3 (2.2-9.8) |

Rabbit

| PET | Aorta SUVmax | 0.80 (0.53-1.11) | 0.54 (0.50-0.78) | 0.67 (0.41-1.07) |
|     | Aorta-to-muscle ratio | 6.0 (4.5-7.6) | 5.5 (4.6-5.7) | 5.7 (4.8-7.4) |

Values are median (interquartile range).

64Cu = copper-64; LOX = lectin-like oxidized low-density lipoprotein receptor; MMR = macrophage mannose receptor; PET = positron emission tomography; SUV = standardized uptake value; VCAM = vascular cell adhesion molecule.

atherosclerotic aortas of rabbits injected with the 64Cu-nanobodies was carried out. In addition to nanobody PET, the multimodal imaging protocol also included T2-weighted-MRI measurement of vessel wall area (Figure 3A, left) and DCE-MRI-based evaluation of vascular permeability (Figure 3A, right). Additionally, an 18F-FDG-PET scan was performed 2 days before the nanobody-PET scan to allow direct comparison between 18F-FDG and the nanobody radiotracers in the same rabbit (Figure 3B, left). Representative PET/MR fusion images of aortas from rabbits injected with the 64Cu-nanobodies recorded between 160 and 170 min p.i. are shown in Figure 3B (right). T2-weighted-based plaque area, DCE-MRI measurements, and 18F-FDG uptake were similar among the 3 groups of rabbits. Overall, these parameters suggest a similar degree of disease burden for all groups. Similar to the mouse studies, we found fast blood clearance with varying organ distributions by ex vivo gamma counting (Online Figures 3A and 3B). Radioactivity concentration in the aorta and aorta-to-muscle, aorta-to-blood, and aorta-to-lung ratios were comparable for all nanobody radiotracers, whereas aorta-to-heart and aorta-to-liver ratios showed significant differences (Online Figure 3C). In concordance with mouse findings, autoradiography of abdominal rabbit aortas showed a heterogeneous radioactivity distribution pattern for 64Cu-VCAM and, especially, 64Cu-MMR (Online Figure 3D). The evaluation of a radiotracer’s potential to discriminate atherosclerotic lesions from healthy segments in the vessel wall should take into account the disease’s heterogeneity. Aorta-to-blood ratios are based on aortic value averages from healthy and diseased segments. To better appreciate the nanobody tracers’ atherosclerosis imaging potential, we conducted a careful autoradiographic analysis (Online Figure 4A). The most diseased segments (MDS) had about 1.5×, 3×, and 4× more counts per unit area than the corresponding atherosclerosis-free, least diseased segments for 64Cu-LOX, 64Cu-VCAM, and 64Cu-MMR, respectively (Online Figures 4B and 4C). Moreover, MDS for 64Cu-MMR contained more than 2× the radioactivity per unit area than the average whole abdominal aorta (Online Figure 4D). For illustrative purposes, we also computed MDS-to-blood and MDS-to-heart ratios (Online Figures 4E and 4F). Collectively, these data suggest that the MMR nanobody has a high atherosclerosis imaging potential. A summary of the key findings from the 64Cu-nanobody tracer studies in mice and rabbits can be found in Table 1.

To investigate whether nanobody tracer accumulation was related to plaque size, inflammation, or permeability, we performed extensive comparative region-by-region analyses between their uptake and the different parameters evaluated by our multi-pronged imaging protocol (Online Figure 5). Interestingly, aortic 64Cu-MMR uptake was not significantly correlated with the uptake of 18F-FDG, but 64Cu-MMR uptake did show a positive correlation with vessel wall area (Online Figure 5A). We also found a significant inverse correlation between 64Cu-VCAM uptake and vessel wall area. Ex vivo radioactivity distribution in the aorta was evaluated by digital autoradiography and compared against the other parameters using a similar analysis (Online Figure 6A). Importantly, significant correlations were found between PET-derived standardized uptake values and radioactivity deposition as quantified from the autoradiographs for all 64Cu-nanobodies, demonstrating the reliability of the imaging-derived values (Online Figure 6B). No correlation was found between any 64Cu-nanobody uptake and vascular permeability, as measured by DCE-MRI, suggesting that their accumulation in the vessel wall is not governed by this parameter (Online Figure 6C).

PET/MR EVALUATION OF ATHEROSCLEROSIS PROGRESSION. Due to its favorable pharmacokinetics and plaque macrophage specificity, the MMR nanobody was further included in a PET/MRI atherosclerosis progression study. To match the nanobody’s short blood circulation time and pursue a translational approach, in the ensuing experiments we used the shorter-lived isotope 68Ga (physical half-life = 68 min). We obtained 68Ga-MMR in high
radiochemical yield and purity. Importantly, no meaningful differences were found between the $^{68}$Ga-labeled VCAM and MMR nanobodies and their $^{64}$Cu-labeled counterparts in preliminary experiments carried out in $\text{Apoe}^{-/-}$ mice (Online Figure 7).

The study also included static $^{18}$F-FDG and $^{18}$F-NaF PET scans on consecutive days before the multiparametric $^{68}$Ga-MMR PET/MRI session (Online Figure 8A). We observed a gradual increase in $^{18}$F-FDG and $^{68}$Ga-MMR PET signal intensities in the aorta as disease progressed (Figure 4A). Interestingly, although $^{18}$F-NaF PET aortic signal was similar between control subjects and rabbits fed a cholesterol-enriched high-fat diet (HFD) for 4 months, a significant increase after 8 months on HFD was found. Aorta-to-muscle ratios showed a similar trend (Online Figure 8B). Finally, vessel wall area and permeability also increased as disease advanced (Figure 4B).

Online Table 3 summarizes the main imaging parameters for the 3 tracers.

To explore the feasibility of coronary imaging, cardiac uptake for the 3 radiotracers was determined by PET to calculate the aorta-to-heart ratios in rabbits with advanced atherosclerosis (8-month

(A) Representative coronal aortic fused PET/MR images for $^{18}$F-FDG (3 h p.i.) (left), $^{68}$Ga-MMR (2 h p.i.) (middle) and $^{18}$F-NaF (1.5 h p.i.) (right), and (B) representative T2W-MRI (left) and DCE-MRI (right) images from healthy and atherosclerotic rabbits (on high-fat diet for 4 months [HFD] or 8 months [BHFD], $n = 3$ per group). (C) Cardiac PET/MR images of the respective tracers and associated aorta-to-heart ratios in rabbits with atherosclerosis (BHFD). (D) Aortic sections taken from healthy control subjects and atherosclerotic rabbits (4HFD or BHFD) and stained with H&E and RAM-11 (macrophages). *$p < 0.05$; $^{18}$F-FDG versus $^{18}$F-NaF. **$p < 0.05$; ***$p < 0.01$. Abbreviations as in Figures 1 to 3.
HFD (Figure 4C). The PET scan showed that $^{18}$F-NaF had the highest ratio due to its low uptake in cardiac tissue, followed by $^{68}$Ga-MMR and $^{18}$F-FDG, whose uptake in the myocardium was relatively high (standardized uptake value 2 to 4 g/ml) despite a 4-h fasting protocol before injection. Similar to $^{64}$Cu-MMR results, vessel wall area was significantly associated with $^{68}$Ga-MMR uptake ($r = 0.55$, $p = 0.0002$), which is indicative of macrophage accumulation in atherosclerosis progression. The $^{68}$Ga-MMR PET images were dominated by a strong kidney signal in all groups, and no significant differences were found in organ uptake for all tracers (kidney, liver, bone marrow—or bone for $^{18}$F-NaF—and spleen) among the 3 groups (Online Figure 8C). Ex vivo quantification of aortic uptake by gamma counting corroborated the in vivo findings (Online Figure 8D, left). Marked differences in radioactivity deposition patterns were also observed between control and atherosclerosis groups by autoradiography (Online Figure 8D, right). Of note, the blood half-life for $^{68}$Ga-MMR was similar in all 3 groups (Online Figure 8E).

Histological evaluation of aortic sections confirmed disease progression as shown by increased plaque area and macrophage content (Figure 4D), as well as microcalcifications (Online Figure 9A), in atherosclerotic aortas and absence of these hallmarks in the control and 4-month HFD groups. Quantitative analysis revealed a significant increase in plaque size, macrophage content, and MMR (CD206) expression as disease progressed (Figures 5A and 5B). Importantly, CD206 immunostaining of diseased aortas correlated significantly with $^{68}$Ga-MMR radioactivity measured by autoradiography (Figure 5C). We found no CD206 staining in the control group, whereas expression was
activity clearance from blood that was mirrored by MRI biodistribution evaluation showed fast radio-reducing radiation exposure. Indeed, in vivo PET/labeling with short-lived isotopes, substantially clear difference among aortic 64Cu-nanobody up-rabbits. However, whereas in rabbits there was no biodistribution patterns were observed in mice and renal clearance for all nanobody tracers. Similar a rapid accumulation in the kidneys, con

DCE-MRI permeability measurements, its uptake tissue of atherosclerotic lesions of adventitial layer and the surrounding perivascular attributed in part to MMR-positive cells in the significance of this imaging approach to longitudinally evaluate disease burden.

DISCUSSION

Three nanobodies targeting 3 well-established markers related to monocyte/macrophage dynamics were screened to identify key features of atherosclerotic lesions. In contrast to long-circulating full-size antibodies (22), the use of radiolabeled nanobodies enables PET vessel wall imaging at earlier time points due to their rapid blood clearance after injection. Conveniently, nanobodies’ shorter circulation times allow their labeling with short-lived isotopes, substantially reducing radiation exposure. Indeed, in vivo PET/MRI biodistribution evaluation showed fast radioactivity clearance from blood that was mirrored by a rapid accumulation in the kidneys, confirming renal clearance for all nanobody tracers. Similar biodistribution patterns were observed in mice and rabbits. However, whereas in rabbits there was no clear difference among aortic 64Cu-nanobody uptakes, in Apoe−/− mice 64Cu-MMR uptake was significantly higher. Although this uptake can be attributed in part to MMR-positive cells in the adventitial layer and the surrounding perivascular tissue of atherosclerotic lesions of Apoe−/− mice (23), in rabbits we did observe an increased plaque uptake compared to control subjects and expression of the mannose receptor within the lesions. These observations likely reflect the differences in lesion composition between the 2 models (24).

Using our newly developed multiparametric atherosclerosis imaging protocol, we noninvasively observed a similar disease burden in all rabbits. Comparative analyses revealed a moderate correlation between vessel wall area and permeability, pointing to a certain degree of association between lesion size and neovascularization. Interestingly, whereas 64Cu-VCAM uptake did not correlate with DCE-MRI permeability measurements, its uptake was negatively associated with vessel wall area, both in vivo and ex vivo. These findings are consistent with the distinct expression of VCAM-1 in early atherosclerotic lesions (25) and may warrant further research into the use of this VCAM-1 nanobody radiotracer to detect such lesions. The MMR nanobody tracer was further included in an atherosclerosis progression study. To enhance translatability, and to match its short blood circulation half-life, we labeled the MMR nanobody with the clinically relevant (26), short-lived isotope 68Ga. This facilitated a unique head-to-head comparison between clinically available radiotracers, namely 18F-FDG and 18F-NaF, and the MMR nanobody radiotracer. Image analysis revealed a significantly higher aortic uptake for 18F-FDG, 18F-NaF, and 68Ga-MMR in rabbits with advanced atherosclerotic lesions as compared to healthy control subjects, which is indicative of increased vessel wall inflammatory activity, microcalcification, and macrophage burden, respectively. MR-based measurements also revealed an increase in vessel wall area and permeability. These findings are consistent with an increased plaque burden, although the 3 radiotracers seemed to accumulate at different locations and/or concentrations throughout the aorta as evidenced by the absence of significant correlations between their respective uptakes. This is in keeping with previous studies reporting a low degree of colocalization between 18F-FDG and 18F-NaF in atherosclerotic lesions (27). Moreover, our histological and autoradiographic analyses of aortic sections showed no significant association between macrophage burden and mineral deposits. Taken together, these data are consistent with a temporal separation between the processes imaged by the 2 tracers, because macrophage-mediated inflammation and mineral deposition are considered hallmarks of early and advanced lesions, respectively. Therefore, these 2 tracers seem complementary and their combined use as a “cocktail” (28) could be of value also in atherosclerosis.

The mannose receptor (MRC1, CD206) has been historically used as a marker for alternatively activated macrophages (29,30). Its expression has been shown in human lesions with intraplaque hemorrhage and in thin cap fibroatheromas (31,32), making it a potential marker of plaque vulnerability. Over the last decades, 18F-FDG has been exploited as a surrogate PET radiotracer for plaque inflammation. Although 18F-FDG is mainly taken up by macrophages (8), other processes than inflammation and other cell types may also contribute to its
accumulation in atherosclerotic plaques (33). Moreover, alternatively activated and inflammatory macrophages have been shown to utilize glucose to a similar extent (34). In this study, we found a weak correlation between 18F-FDG and 64Cu-MMR uptake measured ex vivo, whereas no relationship was found between 64Cu-MMR and HDL uptake, which was used to map macrophages by near infrared fluorescence (NIRF) imaging (35) and did correlate with 18F-FDG uptake. Collectively, these data indicate that different macrophage populations are targeted by these 2 radiotracers, that is, all versus CD206+ macrophages. Ensuing studies will have to elucidate the complex relationships among inflammation, macrophage phenotype, glucose metabolism, and 18F-FDG uptake in the vessel wall.

One of the limitations of atherosclerosis imaging with 18F-FDG is the elevated myocardial uptake, which hinders accurate identification of lesions in the coronary arteries (36). For comparative purposes, PET-derived aorta-to-heart uptake ratios in diseased rabbits were calculated for 18F-FDG, 18F-NaF, and 68Ga-MMR as a measure of their ability to image atherosclerosis in the coronary arteries. Although the MMR nanobody did not show as high a background signal as 18F-FDG, its moderate aorta-to-heart uptake ratio—probably due to the presence of “background” cardiac resident macrophages (37)—may limit its ability to image coronary plaques to areas with significant macrophage burden. In this respect, 18F-NaF has an enormous advantage, as its cardiac uptake is low. However, in this rabbit model, we had to exclude some aortic regions from our analysis due to elevated 18F-NaF uptake in nearby vertebrae. In the future, this might prevent reliable aortic imaging in patients, whereas 18F-FDG and 68Ga-MMR showed lower uptake in the vertebrae aside from a marginal uptake in the bone marrow.

In recent years, the community has witnessed a shift in atherosclerosis research toward an integral disease and away from the individual culprit plaque. Monocyte recruitment and local macrophage proliferation have been identified as key processes in atherosclerotic progression, and recent insights indicate some degree of neural involvement (38). Characterizing all these processes in a longitudinal fashion would enormously benefit from a noninvasive imaging approach. PET is intrinsically a “hot spot” technique and therefore particularly suited to study biological processes systemically (38). From a clinical perspective, noninvasive imaging has already been successfully used to provide surrogate endpoints in clinical trials (9). These often require a large number of participants to ensure a meaningful level of statistical significance is achieved, with long follow-up periods, as the primary endpoint is typically mortality. Robust noninvasive readouts are therefore extremely beneficial as they directly probe treatment response and thereby provide reliable information in a much shorter time frame. In this setting, an imaging approach like the one described here can be of great value. Furthermore, the protocol could be additionally complemented by incorporation of noncontrast T1-weighted MRI to investigate the presence of intraplaque hemorrhage or thrombus (39,40), whereas quantitative evaluation of the fibrous cap and the lipid-rich necrotic core could be performed by T2-weighted MRI (41). Thus, several specific aspects of the disease can be interrogated simultaneously to obtain a more complete representation of the intervention outcome.

CONCLUSIONS

We have translated nanobody-based radiotracer technology to rabbits for the first time and integrated it in a PET/MRI protocol that allows evaluation of several key features of atherosclerosis progression. Our protocol enabled reliable phenotyping of rabbit atherosclerotic lesions over time, as well as extensive comparison of the nanobody probes with different clinical radiotracers. Here, we advocate this multi-parametric imaging approach that may be used to aid in early stage drug development as well as in identification of high-risk patients. We believe that the nanobody tracers presented in this study complement the clinically available tracers 18F-FDG and 18F-NaF and, as attested by the phase I clinical trial of a HER2 nanobody tracer to identify patients with breast cancer (26), their translation is within reach.
