BLACK HOLE – NEUTRON STAR MERGERS AS CENTRAL ENGINES OF GAMMA-RAY BURSTS

H.-Thomas Janka¹, Thomas Eberl¹,², Maximilian Ruffert³, and Chris L. Fryer⁴

Draft version February 17, 2022

ABSTRACT

Hydrodynamic simulations of the merger of stellar mass black hole – neutron star binaries (BH/NS) are compared with mergers of binary neutron stars (NS/NS). The simulations are Newtonian, but take into account the emission and backreaction of gravitational waves. The use of a physical nuclear equation of state allows us to include the effects of neutrino emission. For low neutron star to black hole mass ratios the neutron star transfers mass to the black hole during a few cycles of orbital decay and subsequent widening before finally being disrupted, whereas for ratios near unity the neutron star is already destroyed during its first approach. A gas mass between ∼0.3M⊙ and ∼0.7M⊙ is left in an accretion torus around the black hole and radiates neutrinos at a luminosity of several 10⁵³ erg/s during an estimated accretion time scale of about 0.1 s. The emitted neutrinos and antineutrinos annihilate into e+e− pairs with efficiencies of 1–3% percent and rates of up to ∼2×10⁵² erg/s, thus depositing an energy Eνν~10⁵³ erg above the poles of the black hole in a region which contains less than 10⁻⁵ M⊙ of baryonic matter. This could allow for relativistic expansion with Lorentz factors around 100 and is sufficient to explain apparent burst luminosities Lγ~Eνν/(fΩt) up to several 10⁵³ erg s⁻¹ for burst durations tγ≈0.1–1 s, if the γ emission is collimated in two moderately focussed jets in a fraction fΩ=2ΔΩ/(4π)≈1/100—1/10 of the sky.

Subject headings: binaries: close — black hole physics — gamma-rays: bursts — stars: neutron (ν¯ν) annihilation as potential source of energy for GRBs.

1. INTRODUCTION

BH/NS and NS/NS mergers are discussed as promising candidates for the origin of gamma-ray bursts (GRBs) (e.g., Blinnikov et al. 1984; Eichler et al. 1989; Paczynski 1991; Narayan, Piran, & Shemi 1992; Mészáros 1999; Fryer, Woosley, & Hartmann 1999; Bethe & Brown 1998, 1999), at least for the subclass of less complex and less energetic short and hard bursts (Mao, Narayan, & Piran 1994) with durations of fractions of a second (Popham, Woosley, & Fryer 1999; Ruffert & Janka 1999). Optical counterparts and afterglows of this subclass have not yet been observed. Due to the presence of a region of very low baryon density above the poles of the black hole, BH/NS mergers are considered as more favorable sources than NS/NS mergers (e.g., Portegies Zwart 1998; Brown et al. 1999).

Previous Newtonian SPH simulations of BH/NS mergers using a polytropic equation of state indicate that the neutron star may slowly lose gas in many mass transfer cycles (Kluźniak & Lee 1998; Lee & Kluźniak 1998, 1999). Whether dynamical instability sets in at a minimum separation (Rasio & Shapiro 1994; Lai, Shapiro & Shapiro 1994) or whether stable Roche lobe overflow takes place, however, can depend on the neutron star to black hole mass ratio (Bildsten & Cutler 1992) and the properties of the nuclear equation of state, expressed by the adiabatic index (Uryū & Eriguchi 1999).

In this Letter we report about the first Newtonian BH/NS merger simulations (Eberl 1998) which were done with a realistic nuclear equation of state (Lattimer & Swesty 1991) and which therefore yield information about the thermodynamic evolution and the neutrino emission. They allow one to compare the strength of the gravitational wave (GW) emission relative to NS/NS mergers and to investigate neutrino-antineutrino (ν¯ν) annihilation as potential source of energy for GRBs.

2. NUMERICAL METHODS

The three-dimensional hydrodynamic simulations were performed with a Eulerian PPM code using four levels of nested cartesian grids which ensure a good resolution near the center of mass and a large computational volume simultaneously. Each grid had 64³ zones, the size of the smallest zone was 0.64 or 0.78 km in case of NS/NS and 1.25 or 1.5 km for BH/NS mergers. The zone sizes of the next coarser grid levels were doubled to cover a volume of 328 or 400 km side length for NS/NS and 640 or 768 km for BH/NS simulations. GW emission and its backreaction on the hydrodynamics were taken into account by the method of Blanchet, Damour, & Schäfer (1990) (see Ruffert, Janka, & Schäfer 1996). The neutrino emission and corresponding energy and lepton number changes of the matter were calculated with an elaborate neutrino leakage scheme (Ruffert, Janka, & Schäfer 1996), and νν annihilation around the merger was evaluated in a post-processing step (Ruffert et al. 1997).

3. SIMULATIONS

Table 1 gives a list of computed NS/NS and BH/NS merger models. Besides the baryonic mass of the neutron star and the mass of the black hole, the spins of the neutron stars were varied. “Solid” means synchronously rotating stars, “none” irrotational cases and “anti” counter-rotation, i.e., spin vectors opposite to the direction of the orbital angular momentum. The cool neutron stars have a radius of about 15 km (Ruffert, Janka, & Schäfer 1996) and the runs were started with a center-to-center distance of 42–46 km for NS/NS and with 47 km in case of BH/NS for MBH=2.5M⊙, 57 km for MBH=5M⊙ and 72 km for MBH=10M⊙. The simulations were stopped at a time tsim between 10 ms and 20 ms. The black hole was treated as a point

mass at the center of a sphere with radius \( R_c = 2GM_{\odot}/c^2 \) which gas could enter unimpeded. Its mass and momentum were updated along with the accretion of matter. Model TN10, which is added for comparison, is a continuation of the NS/NS merger model B64 where at time \( t_{\text{sim}} = 10\,\text{ms} \) the formation of a black hole was assumed and the accretion was followed for another 5 ms until a steady state was reached (Ruffert & Janka 1999).

4. RESULTS

4.1. Evolution of BH/NS mergers

Due to the emission of GWs the orbital separation decreases. During its first approach, the neutron star transfers matter to the black hole at huge rates of several 100 up to \( \sim 1000M_\odot/\text{s} \). Within 2–3 ms it loses 50–75% of its initial mass. In case of the 2.5\,M_\odot black hole the evolution is catastrophic and the neutron star is immediately disrupted (Lattimer & Schramm 1974). A mass of 0.2–0.3\,M_\odot remains in a thick disk around the black hole (\( M_d \) in Table 2). In contrast, the orbital distance increases again for \( M_{\text{BH}} = 5\,M_\odot \) and \( M_{\text{BH}} = 10\,M_\odot \) and a significantly less massive neutron star begins a second approach. Again, the black hole swallows gas at rates of more than 100\,M_\odot/\text{s}. Even a third cycle is possible (Fig. 1). Finally, at a distance \( d_{\text{ns}} \) and time \( t_{\text{ns}} \) the neutron star with a mass of \( M_{\text{NS}} \) is destroyed and most of its mass ends up in an accretion disk (Table 2). (In case of NS/NS mergers \( t_{\text{ns}} \) means the time when the two density maxima of the stars are one stellar radius, i.e., \( d_{\text{ns}} = 15\,\text{km} \), apart).

The increase of the orbital separation is connected with a strong rise of the specific (orbital) angular momentum of the gas (Fig. 1). Partly this is due to the fact that the black hole can capture gas with low specific angular momentum first, but mainly because only a fraction of the orbital angular momentum of the accreted gas is fed into spinning up the black hole. This fraction, which is lost for the orbital motion, is proportional to the quantity \( \alpha \) in Fig. 2. Figure 2 is based on the parameterized analysis of non-conservative mass-transfer by Podsiadlowski, Joss, & Hsu (1992) (see also Fryer et al. 1999) assuming that mass ejection from the system is negligible. It shows that disregarding GW emission, the orbital separation can increase for small initial black hole mass only after the neutron star has lost much mass, while for larger initial \( M_{\text{BH}} \) and smaller \( \alpha \) orbital widening is easier. Without GWs the separation increases when \( \alpha < (M_{\text{BH}}-M_{\text{NS}})/(M_{\text{BH}}+M_{\text{NS}}) \). Including angular momentum loss by GWs in the point-mass approximation and using the mass-loss rates from the hydrodynamic models (dashed lines in Fig. 2) yields a qualitative understanding of the behavior visible in Fig. 1 and suggests that \( \alpha \) is between 0.2 and 0.5.

During the merging a gas mass \( \Delta M_{\text{gs}} \) of \( \sim 10^{-4}M_\odot \) (in case of counter-rotation and \( M_{\text{BH}} = 2.5\,M_\odot \)) to \( \sim 0.1M_\odot \) (corotation and \( M_{\text{BH}} = 10\,M_\odot \)) is dynamically ejected (Table 2). In the latter case the associated angular momentum loss is about 7%, in all other cases it is less than 5% of the total initial angular momentum of the system. Another fraction of up to 24% of the initial angular momentum is carried away by GWs. In Table 2 the rotation parameter \( a = J_c/(GM^2) \) is given for the initial state of the binary system (a) and at the end of the simulation (\( a_{\text{sim}} \)) for the remnant of NS/NS mergers or for the black hole in BH/NS systems, respectively, provided the black hole did not have any initial spin. When the whole disk mass \( M_d \) has been swallowed by the Kerr black hole, a final value \( a_{\text{BH}}^c \) (Table 2) will be reached in case of the accretion of a corotating, thin disk with maximum radiation efficiency.

The phase of largest mass flow rate to the black hole (between 2 and 5 ms after the start of the simulations) is connected with a maximum of the GW luminosity \( L_{\text{GW}} \) which reaches up to \( 7 \times 10^{55}\,\text{erg/s} \) (Table 1). The peak values of \( L_{\text{GW}} \) and the wave amplitude \( r_h \) (for distance \( r \) from the source) increase with the black hole mass. The total energy \( E_{\text{GW}} \) radiated in GWs can be as much as \( 0.1M_\odot c^2 \) for \( M_{\text{BH}} = 10\,M_\odot \).

4.2. Neutrino Emission and GRBs

Compositional heating, shear due to numerical viscosity, and dissipation in shocks heat the gas during accretion to maximum temperatures \( kT_{\text{max}} \) of several 10 MeV. Average temperatures are between 5 and 20 MeV, the higher values for the less massive and more compact black holes. At these temperatures and at densities of \( 10^{10}–10^{12}\,\text{g/cm}^3 \) in the accretion flow, electrons are non-degenerate and positrons abundant. Electron neutrinos and antineutrinos are therefore copiously created via reactions \( p+e^-\rightarrow n+\nu_e \) and \( n+e^-\rightarrow p+\bar{\nu}_e \) and dominate the neutrino energy loss from the accreted matter. Dense and hot neutron matter is not completely transparent to neutrinos. By taking into account the finite diffusion time, the neutrino trapping scheme limits the loss of energy and lepton number.

In Table 1 maximum and average values of the luminosities \( (L_{\nu_{\text{max}}}^\text{max} \) and \( L_{\nu_{\text{out}}}^\text{max} \), respectively, the latter in brackets) in the simulated time intervals are listed for \( \nu_e \) and \( \nu_\mu \) and for the sum of all heavy-lepton neutrinos. The latter are denoted by \( \nu_x \equiv \nu_\mu, \bar{\nu}_\mu, \nu_\tau, \bar{\nu}_\tau \) and are mainly produced by \( e^-\rightarrow \nu_x \) annihilation. The total neutrino luminosities \( L_\nu(t) \) (Fig. 3) fluctuate strongly with the varying mass transfer rate to the black hole during the cycles of orbital decay and widening (compare with Fig. 1). The total energy \( E_\nu \) radiated in neutrinos in 10–20 ms is typically several \( 10^{56}\,\text{erg} \). Time averages of the mean energies \( \langle \epsilon \rangle \) of the emitted neutrinos are \( \sim 15\,\text{MeV} \) for \( \nu_e \), \( 20\,\text{MeV} \) for \( \bar{\nu}_e \), and \( 30\,\text{MeV} \) for \( \nu_\mu \). Luminosities as well as mean energies, in particular for smaller black holes, are significantly higher than in case of NS/NS mergers.

At the end of the simulations, several of the BH/NS models have reached a steady state, characterized by only a slow growth of the black hole mass with a nearly constant accretion rate. Corresponding rates \( M_\nu \) are given in Table 2 and are several \( M_\odot/\text{s} \). From these we estimate torus life times \( t_{\text{acc}} = M_\nu/M_\odot \) of 50–150 ms. Values with \( > \) and \( < \) signs indicate cases where the evolution and emission are still strongly time-dependent at \( t_{\text{sim}} \). In these cases the accretion torus around the black hole has not yet developed axial symmetry. In all other cases the effective disk viscosity parameter \( \alpha_{\text{eff}} \sim v_c/v_{\text{Kepler}} \sim 3\,\sqrt{\mathcal{R}}/\langle t_{\text{acc}} \rangle \), evaluated at a representative disk radius of \( \mathcal{R} = 6GM_{\text{BH}}/c^2 \), has the same value, \( 4.5 \times 10^{-3} \). This value is associated with the numerical viscosity of the hydro code (which solves the Euler equations) for the chosen resolution. The further disk evolution is driven by the angular momentum transport mediated by viscous shear forces, which determines the accretion rate. The physical value of the disk viscosity is unknown. The numerical viscosity of our code, however, is in the range where the viscous energy dissipation and the energy emission by neutrinos should be roughly equal, i.e., where the conversion efficiency \( q_{\nu_e} = (\langle L_\nu \rangle/\langle M_\nu c^2 \rangle \) of rest-mass energy to neutrinos is nearly maximal (see Ruffert et al. 1997; Ruffert & Janka 1999).

Assuming that the average neutrino luminosity \( \langle L_\nu \rangle \) at \( t_{\text{sim}} \) is representative for the subsequent accretion phase, we obtain for \( q_{\nu_e} \) numbers between 4 and 6% and total energies \( E_\nu \sim L_\nu t_{\text{acc}} \) around \( 3 \times 10^{52}\,\text{erg} \) (Table 2). Annihilation of neutrino pairs,
$\nu \bar{\nu} \rightarrow e^+ e^-$, deposits energy at rates up to $E_{\nu \bar{\nu}} \sim 2 \times 10^{52}$ erg/s in the vicinity of the black hole (Fig. 4). This corresponds to total energies $E_{\nu \bar{\nu}} \sim E_{\nu \bar{\nu}}$ as high as $\sim 10^{51}$ erg and annihilation efficiencies $q_{\nu \bar{\nu}} = E_{\nu \bar{\nu}} / \langle L_{\nu \bar{\nu}} \rangle$ of 1–3%. These estimates should not change much if the different effects of general relativity on $\nu \bar{\nu}$ annihilation are taken into account in combination (Ruffert & Janka 1999; Asano & Fukuyama 1999), but general relativistic simulations of the merging are very important. More energy could be pumped into the $e^\pm \gamma$ fireball when the black hole rotates rapidly (Popham, Woosley, & Fryer 1999) or if magnetic fields are able to tap the rotational energy of the accretion torus and of the black hole with higher efficiency than $\nu \bar{\nu}$ annihilation does (Blandford & Znajek 1977). This seems to be necessary for the long and very energetic GRBs (Mészáros, Rees, & Wijers 1999; Brown et al. 1999; Lee, Wijers, & Brown 1999).

FIG. 1.— Orbital separation between black hole and neutron star (solid lines) and specific angular momentum of the gas on the grid (dotted lines) as functions of time for Models A2.5, A5, and A10. The steep drop at the end of the solid lines marks the moment when the neutron star is disrupted.
FIG. 2.— Orbital separation as function of neutron star mass for different initial black hole masses and values of parameter $\alpha$ in a simple analytic model (see text). Note that the total mass of the system, $M_{\text{BH}} + M_{\text{NS}}$ is constant along the lines. Mass transfer leads to orbit widening only for $M_{\text{BH}} = 5$ and $10 M_\odot$, whereas GW emission decreases the separation. Combining both effects (dashed lines) qualitatively explains the behavior shown for the hydro simulations in Fig. 1.
Fig. 3.— Total neutrino luminosities as functions of time for BH/NS merger Models A2.5, A5, and A10, and for the NS/NS merger Model A64.
Fig. 4.— Contours of the logarithm of the azimuthally averaged density distribution (dotted lines) of the accretion torus around the black hole (indicated by the white octagonal area at the center) and of the logarithm of the energy deposition rate per cm$^3$ by $\nu\bar{\nu}$ annihilation into $e^+e^-$ pairs (solid lines) for the BH/NS merger Model C2.5 at time 9.56 ms. The contours are spaced in steps of 0.5 dex. The integral energy deposition rate is $2 \times 10^{52}$ erg/s.
