Algebraic Analysis of Rotation Data

Michael F. Adamer, András C. Lőrincz,
Anna-Laura Sattelberger, and Bernd Sturmfels

Abstract

We develop algebraic tools for statistical inference from samples of rotation matrices. This rests on the theory of $D$-modules in algebraic analysis. Noncommutative Gröbner bases are used to design numerical algorithms for maximum likelihood estimation, building on the holonomic gradient method of Sei, Shibata, Takemura, Ohara, and Takayama. We study the Fisher model for sampling from rotation matrices, and we apply our algorithms for data from the applied sciences. On the theoretical side, we generalize the underlying equivariant $D$-modules from $SO(3)$ to arbitrary Lie groups. For compact groups, our $D$-ideals encode the normalizing constant of the Fisher model.

1 Introduction

Many of the multivariate functions that arise in statistical inference are holonomic. Being holonomic roughly means that the function is annihilated by a system of linear partial differential operators with polynomial coefficients whose solution space is finite-dimensional. Such a system of PDEs can be written as a left ideal in the Weyl algebra, or $D$-ideal, for short. This representation allows for the application of algebraic geometry and algebraic analysis, including the use of computational tools, such as Gröbner bases in the Weyl algebra [27, 29].

This important connection between statistics and algebraic analysis was first observed by a group of scholars in Japan, and it led to their development of the Holonomic Gradient Method (HGM) and the Holonomic Gradient Descent (HGD). We refer to [10, 16, 30] and to further references given therein. The point of departure for the present article is the work of Sei et al. [28], who developed HGD for data sampled from the rotation group $SO(n)$, and the article of Koyama [16] who undertook a study of the associated equivariant $D$-module.

The statistical model we examine in this article is the Fisher distribution on the group of rotations, defined in (1) and (2). The aim of maximum likelihood estimation (MLE) is to learn the model parameters $\Theta$ that best explain a given data set. In our case, the MLE problem is difficult because there is no simple formula for evaluating the normalizing constant of the distribution. This is where algebraic analysis comes in. The normalizing constant is a holonomic function of the model parameters, and we can use its holonomic $D$-ideal to derive an efficient numerical scheme for solving the maximum likelihood estimation problem.

The present paper is organized as follows. Section 2 is purely expository. Here, we introduce the Fisher model, and we express its log-likelihood function in terms of the sufficient
statistics of the given data. These are obtained from the singular value decomposition of the sample mean. In Section 3 we turn to algebraic analysis. We review the holonomic $D$-ideal in [28] that annihilates the normalizing constant of the Fisher distribution, and we derive its associated Pfaffian system. Passing to $n \geq 3$, we next study the $D$-ideals on $SO(n)$ given in [16]. First new results can be found in Theorem 3.4 and in Propositions 3.5 and 3.6.

Section 4 is concerned with numerical algorithms for maximum likelihood estimation. We develop and compare Holonomic Gradient Ascent (HGA), Holonomic BFGS (H-BFGS) and a Holonomic Newton method. We implemented these methods in the language R. Section 5 highlights how samples of rotation matrices arise in the sciences and engineering. Topics range from materials science and geology to astronomy and biomechanics. We apply holonomic methods to data from the literature, and we discuss both successes and challenges.

The $D$-ideal of the normalizing constant is of independent interest from the perspective of representation theory, as it generalizes naturally to other Lie groups. The development of that theory is our main new mathematical contribution. This work is presented in Section 6.

2 The Fisher model for random rotations

In this section, we introduce the Fisher model on the rotation group, building on [28]. The group $SO(3)$ consists of all real $3 \times 3$ matrices $Y$ that satisfy $Y^t Y = I_d$ and $\det(Y) = 1$. This is a smooth algebraic variety of dimension 3 in the 9-dimensional space $\mathbb{R}^{3 \times 3}$. See [5] for a study of rotation groups from the perspective of combinatorics and algebraic geometry.

The Haar measure on $SO(3)$ is the unique probability measure $\mu$ that is invariant under the group action. The Fisher model is a family of probability distributions on $SO(3)$ that is parametrized by $3 \times 3$ matrices $\Theta$. For a fixed $\Theta$, the density of the Fisher distribution equals

$$f_{\Theta}(Y) = \frac{1}{c(\Theta)} \cdot \exp(\text{tr}(\Theta^t \cdot Y)) \quad \text{for all } Y \in SO(3).$$

This is the density with respect to Haar measure $\mu$. The denominator is the normalizing constant. It is chosen such that $\int_{SO(3)} f_{\Theta}(Y) \mu(dY) = 1$. This requirement is equivalent to

$$c(\Theta) = \int_{SO(3)} \exp(\text{tr}(\Theta^t \cdot Y)) \mu(dY).$$

This function is the Fourier–Laplace transform of the Haar measure $\mu$; see Remark 6.6. The Fisher model is an exponential family. It is one of the simplest statistical models on $SO(3)$. The task at hand is the accurate numerical evaluation of the integral (2) for given $\Theta$ in $\mathbb{R}^{3 \times 3}$. We begin with the observation that, since integration is against the Haar measure, the function (2) is invariant under multiplying $\Theta$ on the left or right by a rotation matrix:

$$c(Q \cdot \Theta \cdot R) = c(\Theta) \quad \text{for all } Q, R \in SO(3).$$

In order to evaluate (2), we can therefore restrict to the case of diagonal matrices. Namely, given any $3 \times 3$ matrix $\Theta$, we first compute its sign-preserving singular value decomposition

$$\Theta = Q \cdot \text{diag}(x_1, x_2, x_3) \cdot R.$$
Figure 1: A dataset of 28 rotations from a study in vectorcardiography [7], a method in medical imaging. Each point represents the rotation of the unit standard vector on the \(x\)-axis (depicted in red color), the \(y\)-axis (green), and the \(z\)-axis (purple). This sample from the group \(SO(3)\) will be analyzed in Section 5.1.

Sign-preserving means that \(Q, R \in SO(3)\) and \(|x_1| \geq x_2 \geq x_3 \geq 0\). For non-singular \(\Theta\) this implies that \(x_1 > 0\) whenever \(\det(\Theta) > 0\) and \(x_1 < 0\) otherwise.

The normalizing constant \(c(\Theta)\) is the following function of the three singular values:

\[
c(x_1, x_2, x_3) \coloneqq c(\text{diag}(x_1, x_2, x_3)) = \int_{SO(3)} \exp(x_1y_{11} + x_2y_{22} + x_3y_{33}) \mu(dY). \tag{3}\]

The statistical problem we address in this paper is parameter estimation for the Fisher model. Suppose we are given a finite sample \(\{Y_1, Y_2, \ldots, Y_N\}\) from the rotation group \(SO(3)\). We refer to Figure 1 for a concrete example. Our aim is to find the parameter matrix \(\Theta\) whose Fisher distribution \(f_\Theta\) best explains the data. We work in the classical framework of likelihood inference, i.e., we seek to compute the maximum likelihood estimate (MLE) for the given data \(\{Y_1, Y_2, \ldots, Y_N\}\). By definition, the MLE is the \(3 \times 3\) parameter matrix \(\hat{\Theta}\) which maximizes the log-likelihood function. Thus, we must solve an optimization problem.

From our data we obtain the sample mean \(\bar{Y} = \frac{1}{N} \sum_{k=1}^{N} Y_k\). Of course, the sample mean \(\bar{Y}\) is generally not a rotation matrix anymore. We next compute the sign-preserving singular value decomposition of the sample mean, i.e., we determine \(Q, R \in SO(3)\) such that

\[
\bar{Y} = Q \cdot \text{diag}(g_1, g_2, g_3) \cdot R.
\]

The signed singular values \(g_1, g_2, g_3\) together with \(Q\) and \(R\) are sufficient statistics for the Fisher model. The sample \(\{Y_1, \ldots, Y_N\}\) enters the log-likelihood function only via \(g_1, g_2, g_3\).

**Lemma 2.1.** \([28, \text{Lemma } 2]\) The log-likelihood function for the given sample from \(SO(3)\) is

\[
\ell : \mathbb{R}^3 \longrightarrow \mathbb{R}, \quad x \mapsto x_1g_1 + x_2g_2 + x_3g_3 - \log(c(x_1, x_2, x_3)). \tag{4}\]
If \((\hat{x}_1, \hat{x}_2, \hat{x}_3)\) is the maximizer of the function \(\ell\), then the matrix \(\hat{\Theta} = Q diag(\hat{x}_1, \hat{x}_2, \hat{x}_3)R\) is the MLE of the Fisher model (1) of the sample \(\{Y_1, \ldots, Y_N\}\) from the rotation group \(SO(3)\).

Lemma 2.1 says that we need to maximize the function (4) in order to compute the MLE in the Fisher model. We note that a local maximum is already a global one since (4) is a strictly concave function. The maximum is attained at a unique point in \(\mathbb{R}^3\). We shall compute this point using tools from algebraic analysis that are discussed in the next section.

Remark 2.2. The singular values of the sample mean \(\bar{Y}\) are bounded from above and below, namely \(1 \geq |g_1| \geq g_2 \geq g_3 \geq 0\). If \(g_3\) is close to 1, i.e., the average of the rotation matrices is almost a rotation matrix, then the data is typically concentrated about a preferred rotation. In this case the normalizing constant becomes very large and MLE on \(SO(3)\) is numerically intractable; see also Remark 4.3. However, due to the small spread of the data around a point in \(SO(3)\), a matrix valued Gaussian model on \(\mathbb{R}^3\) is an accurate approximation.

3 Holonomic representation

We shall represent the normalizing constant \(\tilde{c}\) by a system of linear differential equations it satisfies. This is known as the holonomic representation of this function. We work in the Weyl algebra \(D\) and in the rational Weyl algebra \(R\) with complex coefficients:

\[
D = \mathbb{C}[x_1, x_2, x_3] \langle \partial_1, \partial_2, \partial_3 \rangle \quad \text{and} \quad R = \mathbb{C}(x_1, x_2, x_3) \langle \partial_1, \partial_2, \partial_3 \rangle.
\]

We refer to [27, 29] for basics on these two noncommutative algebras of linear partial differential operators with polynomial and rational function coefficients, respectively. In order to stress the number of variables, we sometimes write \(D_3\) instead of \(D\) and \(R_3\) instead of \(R\). By a \(D\)-ideal we mean a left ideal in \(D\), and by an \(R\)-ideal a left ideal in \(R\). The use of these algebras in statistical inference was pioneered by Takemura, Takayama, and their collaborators [10, 16, 17, 28, 30]. We begin with an exposition of their results from [28].

The normalizing constant \(\tilde{c}\) is closely related to the hypergeometric function \(0F_1\) of a matrix argument. In [28], annihilating differential operators of \(\tilde{c}\) are derived from

\[
H_i = \partial_i^2 - 1 + \sum_{j \neq i} \frac{1}{x_i^2 - x_j^2} (x_i \partial_i - x_j \partial_j) \quad \text{for } i = 1, 2, 3.
\]  

These in turn can be obtained from Muirhead’s differential operators in [21, Theorem 7.5.6] by a change of variables. In the notation of [27], we have \(H_i \cdot \tilde{c} = 0\) for \(i = 1, 2, 3\). Written in the more familiar form of linear PDEs, this says

\[
\frac{\partial^2 \tilde{c}}{\partial x_i^2} + \sum_{j \neq i} \frac{1}{x_i^2 - x_j^2} (x_i \frac{\partial \tilde{c}}{\partial x_i} - x_j \frac{\partial \tilde{c}}{\partial x_j}) = \tilde{c} \quad \text{for } i = 1, 2, 3.
\]

Note that the operators \(H_i\) are elements in the rational Weyl algebra \(R\). Clearing the denominators, we obtain elements \(G_i\) in the Weyl algebra \(D\) that annihilate \(\tilde{c}\), namely

\[
G_i = \prod_{j \neq i} (x_i^2 - x_j^2) \cdot H_i.
\]  

4
By [28] Theorem 1, the following three additional differential operators in $D$ annihilate $\tilde{c}$:

$$L_{ij} := (x_i^2 - x_j^2)\partial_i\partial_j - (x_i\partial_i - x_j\partial_j) - (x_i^2 - x_j^2)\partial_k. \quad (7)$$

Here the indices are chosen to satisfy $1 \leq i < j \leq 3$ and $\{i, j, k\} = \{1, 2, 3\}$.

Let us consider the $D$-ideal that is generated by the six operators in (6) and (7):

$$I := \langle G_1, G_2, G_3, L_{12}, L_{13}, L_{23} \rangle. \quad (8)$$

In the rational Weyl algebra, we have $RI = \langle H_1, H_2, H_3, L_{12}, L_{13}, L_{23} \rangle$ as $R$-ideals. We enter the $D$-ideal $I$ into the computer algebra system Singular:Plural as follows:

```plaintext
ring r = 0,(x1,x2,x3,d1,d2,d3),dp;
def D = Weyl(r); setring D;
poly L12 = (x1^2-x2^2)*d1*d2 - (x2*d1-x1*d2)-(x1^2-x2^2)*d3;
poly L13 = (x1^2-x3^2)*d1*d3 - (x3*d1-x1*d3)-(x1^2-x3^2)*d2;
poly L23 = (x2^2-x3^2)*d2*d3 - (x3*d2-x2*d3)-(x2^2-x3^2)*d1;
poly G1 = (x1^2-x2^2)*(x1^2-x3^2)*d1^2 + (x1^2-x3^2)*(x1*d1-x2*d2)
+ (x1^2-x2^2)*d3*(x1*d1-x3*d3) - (x1^2-x2^2)*d3*(x1^2-x3^2);
poly G2 = (x2^2-x1^2)*(x2^2-x3^2)*d2^2 + (x2^2-x3^2)*d2*(x2*d2-x1*d1)
+ (x2^2-x1^2)*d3*(x2*d2-x3*d3) - (x2^2-x1^2)*d3*(x2^2-x3^2);
poly G3 = (x3^2-x1^2)*(x3^2-x2^2)*d3^2 + (x3^2-x2^2)*d3*(x3*d3-x1*d1)
+ (x3^2-x1^2)*d2*(x3*d3-x2*d2) - (x3^2-x1^2)*d2*(x3^2-x2^2);
ideal I = L12,L13,L23,G1,G2,G3;
```

We can now perform various symbolic computations in the Weyl algebra $D$. We used the libraries dmodloc [1] and dmod [18], due to Andres, Levandovskyy, and Martín-Morales. In particular, the following two lines confirm that $I$ is holonomic and its holonomic rank is 4:

```plaintext
isHolonomic(I);
holonomicRank(I);
```

The rank statement means algebraically that $\dim_{\mathbb{C}(x_1,x_2,x_3)}(R/RI) = 4$. In terms of analysis, it means that the set of holomorphic solutions to $I$ on a small open ball $U \subset \mathbb{C}^3$ is a 4-dimensional vector space. Here $U$ is chosen to be disjoint from the singular locus

$$\text{Sing}(I) = \{ x \in \mathbb{C}^3 : (x_1^2 - x_2^2)(x_1^2 - x_3^2)(x_2^2 - x_3^2) = 0 \}. \quad (9)$$

We note that the normalizing constant $\tilde{c} = \tilde{c}(x_1,x_2,x_3)$ is a real analytic function on $\mathbb{R}^3 \setminus \text{Sing}(I)$ that extends to a holomorphic function on all of complex affine space $\mathbb{C}^3$.

Using Gröbner bases in the rational Weyl algebra $R$, we find that the initial ideal of $RI$ for the degree reverse lexicographic order is generated by the symbols of our six operators:

$$\text{in}(RI) = \langle \partial_1\partial_2, \partial_1\partial_3, \partial_2\partial_3, \partial_1^2, \partial_2^2, \partial_3^2 \rangle.$$ 

The set of standard monomials equals $S = \{1, \partial_1, \partial_2, \partial_3\}$. This is a $\mathbb{C}(x_1,x_2,x_3)$-basis for the vector space $R/RI$. In this situation, we can associate a Pfaffian system to the $D$-ideal $I$. For the general theory, we refer the reader to [29] and specifically to [27, Equation (23)].

The Pfaffian system is a system of first-order linear differential equations associated to the holonomic function $\tilde{c}$. It consists of three $4 \times 4$ matrices $P_1, P_2, P_3$ whose entries are rational functions in $x_1, x_2, x_3$. We introduce the column vector $C = (\tilde{c}, \partial_1\tilde{c}, \partial_2\tilde{c}, \partial_3\tilde{c})^t$. 
Theorem 3.1. [28 Theorem 2] The Pfaffian system associated to the normalizing constant \( \tilde{c} \) of the Fisher distribution \([1]\) consists of the following three vector equations:

\[
\partial_i \cdot C = P_i \cdot C \quad \text{for } i = 1, 2, 3,
\]

where the matrices \( P_1, P_2, P_3 \in \mathbb{C}(x_1, x_2, x_3)^{4 \times 4} \) are

\[
P_1 = \begin{pmatrix}
0 & 0 & 0 & 0 \\
1 & \frac{x_1(-2x_1^2+x_2^2+x_3^2)}{(x_1^2-x_3)(x_1^2-x_2)} & \frac{x_2}{x_1^2-x_2} & \frac{x_3}{x_1^2-x_3} \\
0 & \frac{x_2}{x_1^2-x_2} & \frac{x_3}{x_1^2-x_2} & 1 \\
0 & \frac{x_3}{x_1^2-x_3} & \frac{x_3}{x_1^2-x_3} & 1
\end{pmatrix}, \quad P_2 = \begin{pmatrix}
0 & 0 & 1 & 0 \\
0 & \frac{x_2}{x_2^2-x_1^2} & \frac{x_1}{x_2^2-x_3^2} & 1 \\
1 & \frac{x_1}{x_2^2-x_3^2} & \frac{x_1}{x_2^2-x_3^2} & 1 \\
0 & 1 & \frac{x_1}{x_2^2-x_3^2} & \frac{x_1}{x_2^2-x_3^2}
\end{pmatrix},
\]

and \( P_3 = \begin{pmatrix}
0 & 0 & 1 & 0 \\
0 & -\frac{x_3}{x_4-x_1} & \frac{x_1}{x_3-x_2} & \frac{x_1}{x_3-x_2} \\
0 & 1 & -\frac{x_3}{x_3-x_2} & \frac{x_1}{x_3-x_2} \\
1 & -\frac{x_1}{x_3-x_2} & \frac{x_1}{x_3-x_2} & \frac{x_1}{x_3-x_2}
\end{pmatrix} \).

We reproduced this Pfaffian system from the operators \( G_1, G_2, G_3, L_{12}, L_{13}, L_{23} \) with the Mathematica package HolonomicFunctions \([15]\). This was done by running Gröbner basis computations in the rational Weyl algebra \( R \) with the degree reverse lexicographic order. See \([27]\, Example 3.4\) for an illustration on how this is done.

The Pfaffian system (10) allows us to recover the \( i \)th partial derivative of the normalizing constant as the first coordinate of the column vector \( P_i \cdot C \). In symbols we have \( \partial_i \cdot \tilde{c} = (P_i \cdot C)_1 \). We make extensive use of this fact when computing the MLE in Section 4. In the same vein, we can recover the Hessian of \( \tilde{c} \) from the Pfaffian system of \( \tilde{c} \) as follows:

\[
\begin{align*}
\partial_1^2 \cdot \tilde{c} &= (P_1 \cdot C)_2, \quad \partial_1 \partial_2 \cdot \tilde{c} = (P_2 \cdot C)_2, \quad \partial_1 \partial_3 \cdot \tilde{c} = (P_3 \cdot C)_2, \\
\partial_2^2 \cdot \tilde{c} &= (P_2 \cdot C)_3, \quad \partial_2 \partial_3 \cdot \tilde{c} = (P_3 \cdot C)_3, \quad \partial_3^2 \cdot \tilde{c} = (P_3 \cdot C)_4.
\end{align*}
\]

This allows for the use of second order optimization algorithms, see Section 4.

An object of interest—from the algebraic analysis perspective—is the Weyl closure of the \( D \)-ideal \( I \). By definition, the Weyl closure is the following \( D \)-ideal which clearly contains \( I \): \( W(I) := RI \cap D \).

In general, it is a challenging problem to compute the Weyl closure of a \( D \)-ideal. This computation is reminiscent of finding the radical of a polynomial ideal, which, according to Hilbert’s Nullstellensatz, consists of all polynomials that vanish on the complex solutions to the given polynomials. The Weyl closure plays a similar role for holonomic functions. It turns out that computing \( W(I) \) is fairly benign for the \( D \)-ideal \( I \) studied in this section.

Lemma 3.2. Let \( I \) be the holonomic \( D \)-ideal in \([8]\). Then the Weyl closure \( W(I) \) is generated by \( I \) and the one additional operator \( x_1 \partial_1 \partial_3 + x_2 \partial_2 \partial_3 + x_3 \partial_3^2 - x_2 \partial_1 - x_1 \partial_2 - x_3 + 2\partial_3 \).

Proof. We used the Singular library dmodloc \([1]\) to compute the Weyl closure of \( I \). We found that \( I \) is not Weyl-closed, i.e., \( I \subsetneq W(I) \). Moreover, by Gröbner basis reductions in the Weyl algebra, we find that adding the claimed operator results in a Weyl-closed ideal. \( \square \)
Following [16,28], we now consider the Fisher distribution on SO(n). The normalizing constant $c(\Theta)$ is defined as in [2], with the integral taken over SO(n) with its Haar measure. Let $D_{n^2}$ be the Weyl algebra whose variables are the entries of the $n \times n$ matrix $\Theta = (t_{ij})$. The corresponding $n \times n$ matrix of differential operators in $D_{n^2}$ is denoted by $\partial = (\partial_{ij})$. The following result was established by Koyama [16], based on earlier work of Sei et al. [28].

**Theorem 3.3.** The annihilator of $c(\Theta)$ is the $D$-ideal generated by the following operators:

\[
d = 1 - \det(\partial), \quad g_{ij} = \delta_{ij} - \sum_{k=1}^{n} \partial_{ik} \partial_{jk} \quad \text{for } 1 \leq i \leq j \leq n, \quad P_{ij} = \sum_{k=1}^{n} (t_{ik} \partial_{jk} - t_{jk} \partial_{ik}) \quad \text{for } 1 \leq i < j \leq n.
\]

Above we omitted half of the equations given in [16, Equation (12)], which is justified by the results in [24, Section 8.7.3]. Also, the operators $P_{ij}$ are induced from left matrix multiplication (as in (26)) rather than right multiplication as in [16, Equation (11)].

A problem that was left open in [16,28], even for $n = 3$, is the determination of the holonomic rank of $J$. We now address this by introducing dimensionality reduction via invariant theory. Let $J'$ be the $D$-ideal generated by the operators $P_{ij}, g_{ij}$. This is the analogue of $J$ for the orthogonal group $O(n)$ in its standard representation in $GL_n(\mathbb{C})$ (see Section 6). Since $O(n)$ has two connected components, the corresponding module in Theorem 6.2 is a direct sum of two simple holonomic $D_{n^2}$-modules. By symmetry, we obtain

\[\text{rank}(J') = 2 \cdot \text{rank}(J).\]  

(12)

The ring of $O(n)$-invariant polynomials on $\mathbb{C}^{n \times n}$ is generated by the $\binom{n+1}{2}$ entries $\{y_{kl}\}_{1 \leq k \leq l \leq n}$ of the symmetric matrix $Y = \Theta^t \cdot \Theta$ (see [24, Section 11.2.1]). These matrix entries $y_{kl}$ are algebraically independent quadratic forms in the $n^2$ unknowns $t_{ij}$.

We now work in the Weyl algebra $D_{\binom{n+1}{2}}$ with the convention $y_{kl} = y_{lk}$ and $\partial_{kl} = \partial_{lk}$. Let $K$ denote the left ideal in that Weyl algebra which is generated by the operators

\[h_{ij} = 2^{k_{ij}} n \cdot \partial_{ij} - \delta_{ij} + \sum_{k,l=1}^{n} 2^{k_{ij} + \delta_{ij}} y_{kl} \cdot \partial_{ik} \partial_{jl} \quad \text{for } 1 \leq i \leq j \leq n.
\]

(13)

**Theorem 3.4.** A holomorphic function is a solution to $J'$ if and only if it is of the form $\Theta \mapsto \phi(y_{ij}(\Theta))$, where $\phi$ is a solution to $K$. In particular, $\text{rank}(K) = 2 \cdot \text{rank}(J)$.

**Proof.** The Lie algebra operators $P_{ij}$ express left invariance under SO(n). The fact that every solution to $J'$ is expressible in $Y$ follows from Luna’s Theorem [19] (see also [11, Section 6.4]). We note that the determinant $\det(\Theta)$ is an $SO(n)$-invariant that we may omit, due to the relation $\det(\Theta)^2 = \det Y$. The $D$-ideal $K$ is the invariant version of $J'$. The operator $h_{ij}$ is derived from $g_{ij}$ by the chain rule. The result therefore follows from (12).

As an application of Theorem 3.4, we answer a question left open in [28, Proposition 2].

**Proposition 3.5.** For $n = 3$, we have $\text{rank}(J) = 4$. 

7
Proof. We used the computer algebra system Macaulay2 \cite{M2}. Unlike for \( \text{rank}(J) \), the calculations for \( \text{rank}(K) \) finished, and we found \( \text{rank}(K) = 8 \). We conclude by Theorem \ref{thm:rank}. □

We next explain how the \( D_{n^2} \)-ideal \( J \) and the \( D_n \)-ideal \( I \) in (8) are connected. The ideal \( I \) is defined as in (8) for all \( n \). We use the construction of the \textit{restriction ideal}. For the general definition see \cite[Equation (13)]{Kontsevich}. In our case, the construction works as follows. We set \( x_i = t_{ii} \) for \( i = 1, \ldots, n \) and we write \( D_n \) for the corresponding Weyl algebra. Then

\[
J_{\text{diag}} := \left( J + \{ t_{ij} : 1 \leq i \neq j \leq n \} \cdot D_{n^2} \right) \cap D_n
\]  

(14)

is the \( D_n \)-ideal obtained by restricting the annihilator of \( c(\Theta) \) to the diagonal entries of the matrix \( \Theta \). Note that the second summand in (14) is a \textit{right} ideal in the Weyl algebra \( D_{n^2} \).

If \( f(\Theta) \) is a function in the \( n^2 \) variables \( t_{ij} \) that is annihilated by \( J \), then the restriction ideal \( J_{\text{diag}} \) annihilates the function \( f(\text{diag}(x_1, \ldots, x_n)) \) in \( n \) variables. Therefore, \( J_{\text{diag}} \) annihilates the restricted normalizing constant \( \tilde{c}(x_1, \ldots, x_n) \). We have the following result.

\textbf{Proposition 3.6.} The following inclusions hold among holonomic \( D_n \)-ideals representing \( \tilde{c} \):

\[
I \subseteq J_{\text{diag}} \subsetneq W(J_{\text{diag}}) \subseteq \text{ann}(D_n)(\tilde{c}).
\]

Equality holds for \( n \leq 3 \) in the rightmost inclusion.

\textit{Proof sketch.} The proof of \cite[Theorem 1]{Kontsevich} shows that \( I \) is contained in \( J_{\text{diag}} \). The middle inclusion is strict by Lemma \ref{lem:restriction}. We have \( W(J_{\text{diag}}) \subseteq \text{ann}(D_n)(\tilde{c}) \) because the annihilator of a smooth function such as \( \tilde{c} \) is Weyl-closed, by an argument spelled out in \cite{Kontsevich}.

The equality on the right for \( n = 3 \) is shown by proving \( W(I) = \text{ann}(D_3)(\tilde{c}) \). We use the following argument and computations. The Fourier transform \( W(I)^{\mathcal{F}} \) is the \( D \)-ideal obtained by switching \( \partial_i \) and \( x_i \) (up to sign). We find that its holonomic rank is 1. We next compute the \textit{holonomic dual} of the module \( D_3/W(I)^{\mathcal{F}} \). This is another \( D_3 \)-module, as defined in \cite[Section 2.6]{Kontsevich}. There is a built-in command for the holonomic dual in Macaulay2 \cite{M2}. Another computation, using localization techniques, verifies that both \( D_3/W(I)^{\mathcal{F}} \) and its holonomic dual are torsion-free as \( \mathbb{C}[x_1, x_2, x_3] \)-modules. These facts imply that \( D_3/W(I)^{\mathcal{F}} \) is a simple \( D \)-module, and hence so is \( D_3/W(I) \). From this we conclude that \( W(I) = \text{ann}(D_3)(\tilde{c}) \). □

We conjecture that the inclusion on the right is an equality for all positive integers \( n \). Using results from Section 6, we can argue that \( W(J_{\text{diag}})^{\mathcal{F}} \) is regular holonomic for any \( n \). It appears that its singular locus is a hyperplane arrangement. The special combinatorial structure encountered in this arrangement gives strong evidence for the conjecture above.

4 Maximum likelihood estimation

We now proceed to finding the maximum of the log-likelihood function of Lemma \ref{lem:maximum} for given datasets. Since the objective function (4) is strictly concave, a local maximum is the global maximizer and attained at a unique point \( \hat{x} = (\hat{x}_1, \hat{x}_2, \hat{x}_3) \in \mathbb{R}^3 \). In order to compute \( \hat{x} \), we run a number of algorithms, each using the holonomic gradient method. This is based on
the results presented in the previous section, especially on Theorem 3.1 and Equation (11). These are used to compute the function values, gradients, and Hessians in each iteration.

A critical step in running any local optimization method is finding a suitable starting point. As mentioned in Section 3, solutions to the $D$-ideal $I$ are analytic outside the singular locus $\text{Sing}(I)$. Starting points need to be chosen in $\mathbb{R}^3 \setminus \text{Sing}(I)$. For the Fisher model on SO(3), the singular locus $\text{Sing}(I)$ is the arrangement of six planes through the origin in $\mathbb{R}^3$. This partitions $\mathbb{R}^3$ into 24 distinct chambers. For the algorithms described below, we choose starting points in each of the 24 connected components of $\mathbb{R}^3 / \text{Sing}(I)$, and we evaluate the vector $C$ at these points. This initialization can be done either via the series expansion method of [28, Section 3.2] or using the package hgm [30] in the statistical software R.

In this section, we present three optimization methods based on algebraic analysis. The simplest is Holonomic Gradient Ascent (HGA). This is a straightforward adaptation of the HGD method in [28]. Second, we introduce a holonomic version of the Broyden–Fletcher–Goldfarb–Shanno (BFGS) method [22, Chapter 6, §1]. BFGS is a quasi-Newton method that requires the gradient and the function value as inputs. Both can be calculated directly using (10). This turns BFGS into Holonomic BFGS (H-BFGS). The third algorithm to be introduced is a Holonomic Newton Method. This second-order method exploits the fact that the Hessian is easy to calculate from (11) and that the objective function is strictly concave.

To get started, we need an expression for the gradient of the log-likelihood function $\ell$ and a Holonomic Gradient Method (HGM) for evaluating that expression. By Lemma 2.1

$$\nabla \ell(x) = \begin{pmatrix} g_1 \\ g_2 \\ g_3 \end{pmatrix} - \frac{1}{\tilde{c}(x)} \cdot \nabla \tilde{c}(x).$$

Note that $C(x) = (\tilde{c}(x), \nabla \tilde{c}(x))^t$. Hence, our task to evaluate $\nabla \ell$ at any point amounts to evaluating the vector-valued function $C$ at any point. This is where the HGM comes in.

In general, we approximate the function $C$ at a point $x^{(n+1)}$ given its value at a previous point $x^{(n)}$. To this end, a path $x^{(n)} \to x^{(n)} + \delta^{(1)} \to x^{(n)} + \delta^{(2)} \to \cdots \to x^{(n)} + \delta^{(K)} \to x^{(n+1)}$ is chosen, where $\delta^{(1)}, \ldots, \delta^{(K)} \in \mathbb{R}^3$ with $\|\delta^{(m+1)} - \delta^{(m)}\|$ sufficiently small. The linear part of the Taylor series expansion of $C$ at $x^{(n)}$ yields the following approximations:

$$C(x^{(n)} + \delta^{(m+1)}) \approx C(x^{(n)} + \delta^{(m)}) + \sum_{i=1}^{3} (\delta^{(m+1)}_i - \delta^{(m)}_i) (\partial_i \cdot C)(x^{(n)} + \delta^{(m)})$$

$$= C(x^{(n)} + \delta^{(m)}) + \sum_{i=1}^{3} (\delta^{(m+1)}_i - \delta^{(m)}_i) P_i \cdot C(x^{(n)} + \delta^{(m)}).$$

We choose a path consisting of points, separated by intervals of size $\Delta t$, on the line segment $x(t) = x^{(n)} (1 - t) + x^{(n+1)} t$ with $t \in [0, 1]$. With this notation, Equation (16) becomes

$$C(x((m+1) \Delta t)) \approx C(x(m \Delta t)) + \sum_{i=1}^{3} (x_i^{(n+1)} - x_i^{(n)}) \Delta t \cdot P_i \cdot C(x(m \Delta t)).$$

If we take the limit $\Delta t \to 0$, then the equation above becomes the differential equation

$$\frac{dC(t)}{dt} = \sum_{i=1}^{3} \frac{\partial x_i}{\partial t} \frac{\partial C}{\partial x_i} = \sum_{i=1}^{3} \left( x_i^{(n+1)} - x_i^{(n)} \right) P_i \cdot C.$$
This ordinary differential equation can be solved using any numerical ODE solver, e.g., an Euler scheme or Runge–Kutta scheme. This leads to the following algorithm.

**Algorithm 1: Holonomic Gradient Method**

**Input:** \( x^{(n)} \), \( x^{(n+1)} \), \( C(x^{(n)}) \), a Pfaffian system \( P_1, P_2, P_3 \)

**Output:** \( C(x^{(n+1)}) \)

1. Set \( x(t) = x^{(n)}(1-t) + x^{(n+1)}t \).
2. Let \( \frac{dC(t)}{dt} = \sum_{i=1}^{3} \frac{\partial x_i}{\partial t} \frac{\partial C}{\partial x_i} = \sum_{i=1}^{3} \left( x_i^{(n+1)} - x_i^{(n)} \right) P_i \cdot C \).
3. Numerically integrate line 2 from \( t = 0 \) to \( t = 1 \).

We employ Algorithm 1 as a subroutine for the holonomic gradient ascent algorithm, which will be described next. HGA is analogous to other gradient ascent/descent methods, however, with the special feature that the gradients are calculated via the HGM algorithm. A description of the algorithm, adapted for data from SO(3), is outlined below.

**Algorithm 2: Holonomic Gradient Ascent**

**Input:** Matrices \( Q \) and \( R \), singular values \( g_1, g_2, g_3 \) and a starting point \( x^{(0)} \in \mathbb{R}^3 \)

**Result:** A maximum likelihood estimate for the data in the Fisher model \( 1 \)

1. Choose a learning rate \( \gamma_n \).
2. Choose a threshold \( \delta \).
3. Evaluate \( C \) at the starting point \( x^{(0)} \).
4. Evaluate \( \nabla \ell \) at the starting point \( x^{(0)} \).
5. Set \( n = 0 \).
6. while \( \max |\nabla \ell(x^{(n)})| < \delta \) do
7. \( x^{(n+1)} = x^{(n)} + \gamma_n \nabla \ell(x^{(n)}) \).
8. Calculate \( C(x^{(n+1)}) \) via HGM using Algorithm 1.
9. Calculate \( \nabla \ell(x^{(n+1)}) \) from \( C(x^{(n+1)}) \).
10. Set \( n = n + 1 \).
11. end
12. Output vector \( x^{(n)} \in \mathbb{R}^3 \) as our approximation for \( (\hat{x}_1, \hat{x}_2, \hat{x}_3) \).
13. Output the rotation matrix \( \hat{\Theta} = Q \cdot x^{(n)} \cdot R \) as our approximation for the MLE.

The given data is a list of rotation matrices \( Y_1, \ldots, Y_N \) in SO(3). As explained in Section 2, we encode these in the singular values \( g_1, g_2, g_3 \) of the sample mean \( \bar{Y} = \frac{1}{N} \sum_{k=1}^{N} Y_k \). Thus, the input for HGA consists primarily of just three numbers \( g_1, g_2, g_3 \). They are used in the evaluation in the first terms of \( \nabla \ell \), as seen in (15). The second term is evaluated by matrix multiplication with \( P_1, P_2, P_3 \), as seen in (10). Part of the input are also the matrices \( Q \) and \( R \) that diagonalize the sample mean \( \bar{Y} \). They are needed in the last step to recover \( \hat{\Theta} \) from \( \hat{x}_1, \hat{x}_2, \hat{x}_3 \) as in Lemma 2.1. The HGA algorithm has two parameters, namely the threshold \( \delta \) which indicates a termination condition, and the learning rate \( \gamma_n \). While \( \delta \) can be chosen freely depending on the desired accuracy, choosing the learning rate can
have significant effects on the convergence of the algorithm. In our computations we chose \( \gamma_n = 10^{-2} \). This can clearly be improved. However, the standard technique of performing line searches to find a good \( \gamma_n \) is not recommended as evaluating \( C \) at a new point is costly.

To employ more advanced methods such as BFGS, and to avoid integrating along a path crossing the singular locus, we use [28, Corollary 1]. This states that the value of \( C \) at a point \((x_1, x_2, x_3)\) can be obtained by integrating the following ODE from \( t = \epsilon \ll 1 \) to \( t = 1 \):

\[
\frac{dC}{dt} = \begin{pmatrix}
0 & x_1 & x_3 \\
x_1 & -2/t & x_3 \\
x_2 & x_3 & -2/t
\end{pmatrix} \cdot C.
\] (18)

Using this approach for calculating \( C \), we can employ BFGS optimization using HGM as a subroutine to calculate the gradients and function values required as inputs. The H-BFGS method achieves much faster convergence rates than the simple HGA algorithm [2].

A final very powerful algorithm for concave (or convex) functions is the Newton method which uses the Hessian matrix. Often, finding the Hessian matrix \( H[\ell(x)] \) of a function is a difficult task. However, using holonomic methods the Hessian is obtained for free via

\[
\partial_i \partial_j \ell = \frac{1}{\epsilon^2} (\partial_i \cdot \tilde{c}) (\partial_j \cdot \tilde{c}) - \frac{1}{\epsilon} \partial_i \partial_j \cdot \tilde{c},
\]

and the relations in (10) and (11). We found that the Newton method,

\[
x^{(n+1)} = x^{(n)} - H[\ell(x)]^{-1} \cdot \nabla \ell(x),
\]

gives the fastest convergence. We refer to this approach as the Holonomic Newton Method.

We implemented the H-BFGS method in a script in the software R. Interested readers may obtain our implementation from the first author. This code is custom-tailored for rotations in 3-space. The function \( C \) is evaluated at the starting point \( x^{(0)} \) using the series expansion method that is described in [28, Section 3.2]. Here we truncate the series at order 41.

**Example 4.1.** We created a synthetic dataset consisting of \( N = 500 \) rotation matrices. These were sampled from the Fisher distribution with parameter matrix

\[
\Theta = \begin{pmatrix}
-1.178 & 0.2804 & 1.037 \\
-0.3825 & 0.9181 & 0.6016 \\
-0.0955 & 0.9037 & 1.695
\end{pmatrix}.
\] (19)

The sample mean and its sign-preserving singular value decomposition are found to be

\[
\bar{Y} = \begin{pmatrix}
-0.2262 & 0.1021 & 0.2260 \\
-0.0233 & 0.0611 & 0.2779 \\
-0.0364 & 0.2802 & 0.3529
\end{pmatrix} = Q \cdot \begin{pmatrix}
0.5946 & 0.0000 & 0.0000 \\
0.0000 & 0.1838 & 0.0000 \\
0.0000 & 0.0000 & 0.1059
\end{pmatrix} \cdot R,
\]

with \( Q = \begin{pmatrix}
-0.4977 & 0.8589 & 0.1211 \\
-0.4518 & -0.1376 & -0.8815 \\
-0.7404 & -0.4934 & 0.4565
\end{pmatrix}, \quad R = \begin{pmatrix}
0.2524 & -0.4808 & -0.8397 \\
-0.9419 & -0.3209 & -0.0993 \\
-0.2217 & 0.8160 & -0.5339
\end{pmatrix} \).
Running H-BFGS on this input, the MLE is found to be
\[ \hat{\Theta} = \begin{pmatrix} -0.8972 & 0.3446 & 0.9682 \\ -0.2392 & 0.7777 & 0.7856 \\ -0.0763 & 0.8664 & 1.616 \end{pmatrix} = Q \cdot \begin{pmatrix} 2.422 & 0.0000 & 0.0000 \\ 0.0000 & 0.7432 & 0.0000 \\ 0.0000 & 0.0000 & -0.3043 \end{pmatrix} \cdot R. \] (20)

While the entries of the MLE \( \hat{\Theta} \) have the correct sign and order of magnitude, the actual values are not very close to those in \( \Theta \). In order to isolate the effect of the sample size on the MLE, we extended the data to 10000 matrices. In the iterations we recorded the Frobenius distance (FD) from \( \hat{\Theta} \) to \( \Theta \) and the logarithm of the likelihood ratio (LR) of the exact parameter and the MLE. Our findings are outlined in the table below.

| # Data | H-BFGS FD | Newton FD | H-BFGS LR | Newton LR |
|--------|-----------|-----------|-----------|-----------|
| 1000   | 0.2136    | 0.2136    | 0.07006   | -0.0007   |
| 2000   | 0.1145    | 0.1145    | 0.08828   | -0.0013   |
| 3000   | 0.1155    | 0.1155    | 0.07837   | -0.0012   |
| 4000   | 0.1485    | 0.1485    | 0.08185   | -0.0014   |
| 5000   | 0.1700    | 0.1700    | 0.07439   | -0.0009   |
| 6000   | 0.1247    | 0.1247    | 0.07325   | -0.0006   |
| 7000   | 0.1321    | 0.1321    | 0.07248   | -0.0006   |
| 8000   | 0.1011    | 0.1011    | 0.07294   | -0.0003   |
| 9000   | 0.0985    | 0.0985    | 0.07127   | -0.0002   |
| 10000  | 0.0838    | 0.0838    | 0.07219   | -0.0002   |

In our experiments we found that the convergence in likelihood ratio and Frobenius distance is slow. It appears that, in general, the MLE problem is not very well conditioned.

**Remark 4.2.** The authors in [28] report that the HGD algorithm becomes numerically unstable when it is close to the singular locus of the Pfaffian system. They recommend picking a starting point in the same connected component of \( \mathbb{R}^3 \setminus \text{Sing}(f) \) where the MLE is suspected. In contrast, our computations suggest that the output of the HGA does not depend on the connected component which the starting point lies in, when a sufficiently stable numerical integration method (e.g. `lsode` from the R package `deSolve`) is chosen in Algorithm 1.

**Remark 4.3.** The sample mean matrix \( \bar{Y} \) lies in the convex hull of the rotation group. This convex body, denoted \( \text{conv}(\text{SO}(3)) \), was studied in [26, Section 4.4], and an explicit representation as a spectrahedron was given in [26, Proposition 4.1]. It follows from the theory of orbitopes [26] that the singular values of matrices in \( \text{conv}(\text{SO}(3)) \) are precisely the triples that satisfy \( 1 \geq |g_1| \geq g_2 \geq g_3 \geq 0 \). These inequalities define two polytopes, which are responsible for the facial description of \( \text{conv}(\text{SO}(3)) \) found in [26, Theorem 4.11].

We can think of the MLE as a map from the interior of the orbitope \( \text{conv}(\text{SO}(3)) \) to \( \mathbb{R}^3 \). Using the singular value decomposition, we restricted this map to the open polytopes given by \( 1 > |g_1| > g_2 > g_3 > 0 \). Note that the coordinates of the vector \( \hat{x} \) goes off to infinity as the maximum of \( \{g_1, g_2, g_3\} \) approaches 1. This follows from [14, Equation (4.12)], where the analogue for \( \text{O}(n) \) was derived. This divergence can cause numerical problems.
In this section, we have turned the earlier results on $D$-ideals into numerical algorithms. This is just a first step. The success of any local method relies heavily on a clear understanding of the numerical analysis that is relevant for the problem at hand. A future study of condition numbers from the perspective of holonomic representations would be desirable.

5 Rotation data in the sciences

Rotation data arise in any field of science in which the orientation of an object in 3-space is important. Occurrences include a diverse number of research areas such as medical imaging, biomechanics, astronomy, geology, and materials science. In this section, we apply our methods to a prominent dataset of vectorcardiograms and to biomechanical data. We also review previous findings on rotation data in astronomy, geology, and materials science.

5.1 Medical imaging

One important occurrence of rotational data in the applied sciences stems from medical imaging, and more precisely from vectorcardiography. In that field, the electrical forces generated by the heart are studied and their magnitude and direction are recorded. The dataset presented in [7] is a famous example of directional data. It contains the orientation of the vectorcardiogram (VC) loop of 98 children aged 2 − 19. In particular, the orientation is measured using two different techniques. Both measurements are given in the form of two vectors. The first identifies the VC loop of greatest magnitude and the second is the normal direction to the loop. We add as a third vector the cross product of the magnitude and normal vector to form a right handed set and, therefore, a rotation matrix.

This dataset has been used to exemplify a range of methods in directional statistics, see, e.g., [23]. We applied the optimization methods from Section 4 to the same dataset. In other words, we computed the maximum of the log-likelihood function (4) for the orientations of the VC loop. In order to match our analysis with the results of [23], we only consider the 28 data points of the boys aged 2 − 10. A colorful illustration of the action of these 28 rotation matrices on the coordinate axes is shown in Figure 1.

We now proceed to the MLE. The sample mean has the singular valued decomposition

$$\hat{Y} = \begin{pmatrix} 0.6868 & 0.5756 & 0.1828 \\ 0.5511 & -0.7372 & -0.0045 \\ 0.1216 & 0.1417 & -0.8630 \end{pmatrix} = Q \cdot \begin{pmatrix} 0.9469 & 0.0000 & 0.0000 \\ 0.0000 & 0.8962 & 0.0000 \\ 0.0000 & 0.0000 & 0.8737 \end{pmatrix} \cdot R,$$  \hspace{1cm} (21)

where

$$Q = \begin{pmatrix} 0.6112 & 0.7636 & 0.2079 \\ -0.7498 & 0.4748 & 0.4608 \\ 0.2532 & -0.4376 & 0.8628 \end{pmatrix}, \quad R = \begin{pmatrix} 0.03941 & 0.99324 & -0.1092 \\ 0.81778 & 0.03072 & 0.5747 \\ 0.57418 & -0.11194 & -0.8110 \end{pmatrix}.$$  \hspace{1cm} (22)

By forming the matrix product $QR$ we recover the result of [23]. The matrix $QR$, however, is only one part of the MLE as described in [14]. By using H-BFGS, we can find the full MLE of the Fisher model. We compared H-BFGS to other methods. For that, we estimated
$x_1, x_2, x_3$ with a BFGS optimization of the log-likelihood using the series expansion of the normalizing constant. We then compare the resulting estimate to the output of H-BFGS.

The H-BFGS algorithm finds the MLE

$$\hat{x}_1 = 20.072407, \quad \hat{x}_2 = 12.513841, \quad \hat{x}_3 = -6.510704,$$

which corresponds to a log-likelihood of $\hat{\ell} = 3.97299$. The runtime of the algorithm is highly dependent on the number of non-zero terms in the series expansion for $\tilde{c}$. In this calculation, the first 6000 non-zero terms are used and the runtime is about 4 seconds. The classical BFGS method is not convergent if only the first 6000 non-zero terms are used. Hence, we need to truncate the series expansion at higher order. If we use the first 48000 non-zero terms, then the series expansion BFGS method finds the MLE

$$\hat{x}_1 = 17.604156, \quad \hat{x}_2 = 10.024591, \quad \hat{x}_3 = -3.881811,$$

which gives $\hat{\ell} = 3.96330$. The computation takes about 20 seconds. Hence, the holonomic BFGS outperformed the classical method by finding a better likelihood value in much shorter time.

### 5.2 Biomechanics

Rotational data is ubiquitous in the biomedical sciences. A prominent experiment in this area is the human kinematics study of [25]. In this experiment, the rotations of four different upper body parts were tracked while the subject was drilling holes into six different locations of a vertical panel. In [4], this dataset was studied and maximum likelihood and Bayesian point estimates for the orientation of the wrist were obtained and credible regions constructed.

A further experiment concerns the heel orientation of primates. In the experiments, the rotation of the calcaneus bone (the heel) and the cuboid bone, which is horizontally adjacent to the heel and closer to the toes, was measured. A load was applied to three sedentary primates, a human, a chimpanzee, and a baboon and the rotation of their ankle was recorded. While the data is actually a time series, the simplifying assumption of independent identically distributed data is made in its analysis [3]. We study this dataset which was kindly provided by Melissa Bingham. The sample mean for the human data equals

$$\bar{Y} = \begin{pmatrix} -0.1013 & -0.9127 & -0.3811 \\ 0.3275 & -0.3895 & 0.8535 \\ -0.9335 & -0.0358 & 0.3475 \end{pmatrix} = Q \cdot \begin{pmatrix} 0.9997 & 0.0000 & 0.0000 \\ 0.0000 & 0.9926 & 0.0000 \\ 0.0000 & 0.0000 & 0.9923 \end{pmatrix} \cdot R, \quad (23)$$

with

$$Q = \begin{pmatrix} 0.4771 & 0.8753 & -0.0791 \\ -0.4320 & 0.1552 & -0.8884 \\ -0.7654 & 0.4580 & 0.4521 \end{pmatrix} \quad \text{and} \quad R = \begin{pmatrix} 0.5248 & -0.2399 & -0.8167 \\ -0.4690 & -0.8822 & -0.0422 \\ -0.7104 & 0.4051 & -0.5754 \end{pmatrix}.$$

We see on the right hand side in (23) that the singular values for this dataset only differ in the third significant figure and the smallest singular value is approximately 1. We found that the normalizing constant gets too large to be computed directly. Indeed, our simulations returned a value error when $\tilde{c} \approx 10^{308}$. This is a serious numerical issue, arising in any MLE
algorithm that attempts to directly calculate $\tilde{c}$ when the sample mean is almost a rotation matrix. Singular values close to one imply that the samples are concentrated on the unit sphere. One could either use a rotational Maxwell distribution [13] as a local model or the approximation used in [3]. The data for the baboon and the chimpanzee show similar traits.

We found that progress can be made by applying a gauge transform in Equation (18), aimed at scaling the input for H-BFGS. Let $\lambda_0$ be the largest eigenvalue of

$$A = \begin{pmatrix}
0 & x_1 & x_2 & x_3 \\
x_1 & 0 & x_3 & x_2 \\
x_2 & x_3 & 0 & x_1 \\
x_3 & x_2 & x_1 & 0
\end{pmatrix}.$$ We can derive an ODE for the function $D = C \exp(-\lambda_0 t)$ from Equation (18). The function $D$ is guaranteed to have smaller values than $C$. Furthermore, the ratio $(\partial_i \cdot \tilde{c})/\tilde{c} = C_i/C_0 = D_i/D_0$ is invariant. Despite being able to compute $\log(\tilde{c})$ using the gauge transformation, MLE becomes very unstable due to the numerical accuracy required. Finding the MLE from a random starting point using H-BFGS proved intractable. However, using the asymptotic formula of [14] to provide a suitable starting point for H-BFGS, we found the MLE $\hat{x}_1 = 5543.106$, $\hat{x}_2 = 3753.078$, $\hat{x}_3 = -3685.242$ corresponding to a log-likelihood of $\hat{\ell} = 10.5934$. The asymptotic formula yielded an MLE of $\hat{x}_1 = 5543.102$, $\hat{x}_2 = 3753.025$, $\hat{x}_3 = -3685.298$ and $\hat{\ell} = 10.52366$. Hence, H-BFGS finds a slightly better MLE than the asymptotic formula.

5.3 Astronomy and geology

Astronomical applications of the matrix Fisher model on SO(3) are often concerned with the orbits of near earth objects [20, 28]. Such objects are comets or asteroids in an elliptical orbit around the sun with the sun in their focus. The data comes as sets of vectors in $\mathbb{R}^3$ taking the sun as the origin. The first vector, $X_1$, is the perihelion direction, which points to the location on the orbit closest to the sun. The second vector, $X_2$, is the unit normal to the orbit. Together with their cross product these vectors form a right handed set. Therefore, they define a rotation matrix. Questions of astronomical interest are whether the perihelion direction is uniformly distributed on the sphere and whether the orbit orientations are uniform on SO(3). To answer the latter question the Raleigh statistic can be used [20, 28].

Sei et al. [28] studied a dataset of rotations representing 151 comets and 6496 asteroids. They computed maximum likelihood estimates using the holonomic gradient method and also series expansions. The Raleigh statistic for the dataset was calculated and the null hypothesis of a uniform distribution was strongly rejected. Further, the hypothesis of the data originating from a Fisher distribution on a Stiefel manifold was tested against the hypothesis of SO(3), and the evidence strongly suggested to reject the Stiefel manifold.

Rotations arise in geology and earth sciences in the study of earthquake epicenters [13] and the analysis of plate tectonics [6]. Davis and Titus [6] studied a dataset of the deformation of a shear zone in northern Idaho. However, this was done in the context of invalidating a geology inspired model that had been used previously to explain the shear deformations.

Kagan [13] studied rotational data describing the earthquake focal mechanism orientation. Various models, including the Fisher model, were discussed in this article. However,
the Fisher model was dismissed due to the difficulty of normalization for small spread data as discussed in Remark 2.2. The alternative model used in [13] was a rotational Maxwell distribution as a local approximation. Our results offer a chance to revisit the Fisher model.

5.4 Materials science

One important source of rotational data is materials science, where patterns from electron backscatter diffraction (EBSD) are analyzed (see, e.g., [2]). This type of data provides information about the orientation of grains within a material. Crystal orientation has important implications on the properties of polycrystalline materials. One issue with EBSD data is the fact that orientations of the crystals can only be determined within a coset of the crystallographic group the grain belongs to. This is due to the fact that a crystal is a lattice and every lattice comes with certain translational and rotational symmetries. Orientations can only be determined up to the rotational invariance of the lattice. Hence, the data, although giving information about rotations, is strictly speaking not on SO(3), but on its quotient by a discrete symmetry subgroup. To adapt our analysis, an appropriate parametrization or embedding for such a quotient needs to be found. This, however, is beyond the scope of this paper and is left for future work. Before going to such manifolds, we start with Lie groups.

6 Compact Lie groups

The Fisher model on SO(n) generalizes naturally to other compact Lie groups. We define the Fisher distribution and the normalizing constant as in (1) and (2), but with integration over the Haar measure on the Lie group. In this section, we introduce these objects and their holonomic representation. In particular, we establish the analogue of Theorem 3.3 for compact Lie groups. This opens up the possibility of applying algebraic analysis to data sampled from manifolds other than SO(n) provided these have the structure of a group.

Let G be a compact connected Lie group and fix a real representation \( \pi : G \to \text{GL}_n(\mathbb{R}) \). We can assume that \( \pi \) is injective, i.e., the representation is faithful. We note that any compact Lie group admits a faithful representation [24, Section 8.3.4]. The matrix group \( \pi(G) \subset \mathbb{R}^{n \times n} \) is a closed algebraic subvariety (see [24, Section 8.7]). If one starts with a complex representation instead, the situation can be studied in the polynomial ring over \( \mathbb{C} \).

For our algebraic approach, the ambient setting is the complex affine space \( X := \mathbb{C}^{n \times n} \). The complexification \( G_C \) of our group \( G \) is a complex connected reductive algebraic group [24, Section 8.7.2]. The extension \( \pi : G_C \to X \) is a closed embedding. Its image, the matrix group \( \pi(G_C) \), is the complex affine variety in \( X \), cut out by the same polynomials as the ones defining \( \pi(G) \). We denote by \( I_G \) the ideal generated by these polynomials in \( \mathbb{C}[X] \). The quotient ring \( \mathbb{C}[G] := \mathbb{C}[X]/I_G \) is the ring of polynomial functions on the group \( \pi(G_C) \).

Let \( \mathfrak{g} \) denote the complex Lie algebra of \( G_C \). This is the complexification of the real Lie algebra of the given Lie group \( G \). We write \( U(\mathfrak{g}) \) for the universal enveloping algebra of \( \mathfrak{g} \). For any affine variety, one can define the ring of algebraic differential operators on that variety. This is generally a complicated object, but things are quite nice in our case.
Let $D_G$ denote the ring of differential operators on $G_C$. We have natural inclusions
\[ g \subset U(g) \subset D_G \quad \text{and} \quad \mathbb{C}[G] \subset D_G. \]
These inclusions exhibit desirable properties. Namely, we have canonical isomorphisms
\[ D_G \cong \mathbb{C}[G] \otimes U(g) \cong U(g) \otimes \mathbb{C}[G]. \tag{24} \]
This holds because left (or right) invariant vector fields of $G_C$ trivialize the tangent bundle. Recall that $G_C$ acts on $X = \mathbb{C}^{n \times n}$ by left matrix multiplication via $\pi$. Through this action, elements in the Lie algebra $g$ induce vector fields on $X$. This gives an injective map
\[ \phi : U(g) \hookrightarrow D_{n^2}. \tag{25} \]

We now proceed to describing the algebra map $\phi$ explicitly. Fix an arbitrary element $\xi \in g$. Let $-M_\xi$ be the $n \times n$ matrix corresponding to $\xi$ via the inclusion $g \hookrightarrow \mathfrak{gl}(n)$. The following is the vector field encoding the Lie algebra action of $M_\xi$ on the space $\mathfrak{gl}(n) \cong \mathbb{C}^{n \times n}$:
\[ \phi(\xi) = \sum_{i,j=1}^n (M_\xi)_{ij} \cdot \sum_{k=1}^n t_{jk} \partial_{ik} \in D_{n^2}. \tag{26} \]

**Example 6.1.** Let $G = SO(n)$ and $\pi : G \to GL_n(\mathbb{R})$ the standard representation on $\mathbb{R}^n$. The associated Lie algebra $g$ is the space of skew-symmetric $n \times n$ matrices over $\mathbb{C}$. A canonical basis of $g$ consists of the rank 2 matrices $e_{ij} - e_{ji}$ for $1 \leq i < j \leq n$. The operator $P_{ij} \in D_{n^2}$ in Theorem 3.3 is Fourier dual to the vector field $\phi$ if we take $\xi = e_{ij} - e_{ji}$.

As seen in [12, Section 1.3], the morphism of varieties $\pi : G_C \to X$ induces a pushforward functor of $D$-modules $\pi_+ : \text{Mod}(D_G) \to \text{Mod}(D_{n^2})$ satisfying the following key property.

**Theorem 6.2.** If we regard $\mathbb{C}[G]$ as a left $D_G$-module, then we have the isomorphism
\[ \pi_+(\mathbb{C}[G]) \cong D_{n^2}/(\langle I_G, \phi(g) \rangle). \]
In particular, this quotient is a regular holonomic simple $D_{n^2}$-module.

**Proof.** By (24), we have the following isomorphism of right $D_G$-modules:
\[ \mathbb{C}[G] \cong \mathbb{C} \otimes_{U(g)} D_G. \tag{27} \]
On the right, $\mathbb{C}$ denotes the trivial representation of the universal enveloping algebra $U(g)$.

Let $D_{G \to X} := \mathbb{C}[G] \otimes_{\mathbb{C}[X]} D_X$ denote the transfer bimodule. This is a left $D_G$-module and a right $D_X$-module. Since the action of $g$ extends to the whole space $X$, we have $\mathbb{C}[G] \cong \mathbb{C}[X]/I_G$ as $g$-modules, and the left $U(g)$-structure of $D_{G \to X}$ is induced by the Leibniz rule via the map (25) on the second factor. We obtain the isomorphism of bimodules
\[ D_{G \to X} \cong D_X/(I_G \cdot D_X). \tag{28} \]
By (27) and (28), we have the following isomorphisms of right $D_X$-modules:
\[ \pi_+(\mathbb{C}[G]) := \mathbb{C}[G] \otimes_{D_G} D_{G \to X} \cong (\mathbb{C} \otimes_{U(g)} D_G) \otimes_{D_G} D_{G \to X} \cong \mathbb{C} \otimes_{U(g)} D_X/(I_G \cdot D_X) \cong D_X/(\langle I_G + \phi(g) \rangle \cdot D_X). \]
The fist claim now follows by switching to left $D_X$-modules. By Kashiwara’s Equivalence Theorem [12, Section 1.6], the module $D_X/(\langle I_G, \phi(g) \rangle)$ is regular holonomic and simple. \qed
Remark 6.3. The assumption that $G$ is compact is not needed in Theorem 6.2. The proof works for any representation $\pi : H \to \text{GL}_n(\mathbb{C})$ of a complex connected algebraic group such that $\pi(H)$ is closed in $\mathbb{C}^{n \times n}$. Such a representation exists for all semi-simple groups $H$. Another natural setting is that of orbits of a compact group $G$ acting linearly on a real vector space, with left-invariant measures used in Corollary 6.5. In our view, the theory of orbitopes [26] should be of interest for statistical inference with data sampled from orbits.

Remark 6.4. Here is a more conceptual argument for Theorem 6.2. The $D$-module $M = D_{n^2} / \langle I_G, \phi(g) \rangle$ is equivariant and supported on $\pi(G) \subset \mathbb{C}^{n \times n}$. By Kashiwara’s Equivalence Theorem, it is the pushforward of a coherent equivariant $D$-module on $G$. This is a direct sum of copies of the module $\mathbb{C}[G]$, by the Riemann–Hilbert Correspondence. Hence, $M$ is a direct sum of copies of $\pi_\pm(\mathbb{C}[G])$. The existence of a unique left-invariant measure on $G$ implies that there is only one such summand in $M$.

Let $\mu_\pi$ be the distribution on $\mathbb{R}^{n \times n}$ given by integration against the Haar measure on $G$.

Corollary 6.5. The annihilator in $D_{n^2}$ of this distribution equals

$$\text{Ann}_{D_{n^2}}(\mu_\pi) = \langle I_G, \phi(g) \rangle.$$ 

Proof. Since supp($\mu_\pi$) = $\pi(G)$, we have $I_G \subset \text{Ann}_{D_{n^2}}(\mu_\pi)$. Since $\mu_\pi$ is a left-invariant distribution, we have also $\phi(g) \subset \text{Ann}_{D_{n^2}}(\mu_\pi)$. By Theorem 6.2, the $D$-ideal $\langle I_G, \phi(g) \rangle$ is a maximal left ideal in $D_{n^2}$, since its quotient is simple. It is therefore equal to $\text{Ann}_{D_{n^2}}(\mu_\pi)$. \qed

The following observation establishes the connection to statistics, as in [16, Section 4].

Remark 6.6. The Fourier–Laplace transform of $\mu_\pi$ has a complex analytic continuation to a holomorphic function on $\mathbb{C}^{n \times n}$ by the Paley–Wiener–Schwartz Theorem, namely

$$c(\Theta) = \int_G \exp(\text{tr}(\Theta^T \pi(Y)))\mu(dY). \quad (29)$$

This is the normalizing constant of the Fisher distribution on the group $\pi(G) \subset \text{GL}_n(\mathbb{R})$. Note that this can be defined for a complex representation $\pi(G) \subset \text{GL}_n(\mathbb{C})$ as well.

The Fourier transform, denoted by $(\bullet)^F$, switches the operators $t_{ij}$ and $\partial_{ij}$ in the Weyl algebra $D_{n^2}$, with a minus sign involved. We consider the image of the $D$-ideal in Corollary 6.5 under this automorphism of $D_{n^2}$. This image is a $D$-ideal $J_\pi$ that is defined over $\mathbb{R}$:

$$J_\pi = \langle I_G, \phi(g) \rangle^F. \quad (30)$$

The following result generalizes Theorem 3.3 to compact Lie groups other than SO($n$).

Corollary 6.7. The $D$-module $D_{n^2}/J_\pi$ is simple holonomic and $\text{Ann}_{D_{n^2}}(c(\Theta)) = J_\pi$.

Proof. By Corollary 6.5, Remark 6.6, and the defining property of the Fourier transform, we see that $J_\pi$ annihilates the integral in (29). The proof concludes by recalling that the Fourier transform induces an auto-equivalence on the category of (holonomic) $D_{n^2}$-modules. \qed
We saw in Section 5 that sampling from SO(3) is ubiquitous in the applied sciences. It would be worthwhile to explore such scenarios also for other matrix groups $\pi(G)$, and to apply holonomic methods to maximum likelihood estimation in their Fisher model.

One promising context for data applications is the unitary groups in quantum physics.

**Example 6.8.** The compact group $G = SU(2)$ consists of complex $2 \times 2$ matrices of the form

$$
\begin{pmatrix}
\alpha & \beta \\
-\beta & \alpha
\end{pmatrix},
$$

with $|\alpha|^2 + |\beta|^2 = 1$. \hfill (31)

Note that $G$ is a double cover of SO(3). While the odd-dimensional (complex) representations of $G$ descend to real-valued representations of SO(3), this is not true for the even-dimensional (spin) representations. Consider the standard representation $G \subset C^{2 \times 2}$.

The complexification of the matrix group in (31) is simply the group $SL_2(C) \subset C^{2 \times 2}$.

The associated (maximal, holonomic) ideal $J_\pi$ is generated by the following four operators:

$$
d = \det(\partial) - 1,
$$

$$
h = t_{11}\partial_{11} + t_{12}\partial_{12} - t_{21}\partial_{21} - t_{22}\partial_{22},
$$

$$
e = t_{21}\partial_{11} + t_{22}\partial_{12},
$$

$$
f = t_{11}\partial_{21} + t_{12}\partial_{22}.
$$

A computation shows that rank $J_\pi = 2$ and $\text{Sing}(J_\pi) = \{ \Theta \in C^{2 \times 2} | \det(\Theta) = 0 \}$. The Lie algebra operators $e, f, h$ ensure that every holomorphic solution to $J_\pi$ is $SL_2$-invariant.

By [19], every solution has the form $\Theta \mapsto \phi(\det(\Theta))$, for some analytic function $\phi$ in a domain of $C^\ast$. This is annihilated by $d$ (hence, by $J_\pi$) if and only if $\phi(x)$ is annihilated by

$$
x\partial^2 + 2\partial - 1 \in D_1.
$$

This has only one (up to scaling) entire solution $\phi$, with series expansion at $x = 0$ given by

$$
\phi(x) = \sum_{n=0}^{\infty} \frac{1}{n! \cdot (n+1)!} x^n.
$$

By comparing constant terms, we conclude that $c(\Theta) = \phi(\det(\Theta))$. It is straightforward to generalize the above considerations to the fundamental representation of the special unitary group $SU(m)$ for any $m \geq 1$. In that setting, we find that rank($J_\pi$) = $m$.

In conclusion, the $D$-ideal $J_\pi$ is an interesting object that deserves further study, not just for the rotation group SO($n$), but for arbitrary Lie groups $G$. Sections 3 and 6 offer numerous suggestions for future research. For instance, what is the holonomic rank of $J_\pi$? Furthermore, it would be desirable to experiment with data sampled from groups $G$ other than SO(3), so as to broaden the applicability of algebraic analysis in statistical inference.

**Acknowledgments.** We thank Mathias Drton for helpful discussions on statistics, Ralf Hielscher for discussions on materials science, and Max Pfeffer for improvements in our numerical methods. We are grateful to Nobuki Takayama and his collaborators for many insightful discussions, and to Charles Wang for getting us started on the material for SO($n$).
