ABSTRACT: We apply the recently proposed quantum extremal surface construction to calculate the Page curve of the eternal Reissner-Nordström black holes in four dimensions. Without the island, the entropy of Hawking radiation grows linearly with time, which results in the information paradox for the eternal black holes. By extremizing the generalized entropy that allows the contributions from the island, we find that the island extends outside the horizon of the Reissner-Nordström black hole. When taking into the effect of the islands, it is shown that the entanglement entropy of Hawking radiation at late times for a given region far from the black hole horizon reproduces the Bekenstein-Hawking entropy of Reissner-Nordström black hole with an additional term representing the effect of the matter fields. The result is consistent with the finiteness of the entanglement entropy for the radiation from an eternal black hole and resolves the information paradox for this case.
1 Introduction and motivation

The information issue of black holes is a fundamental problem in several most important fields of physics—quantum mechanics, thermodynamics and the theory of general relativity, and is essential for our understanding of quantum gravity [1–4]. Recently, tremendous progress has been made to provide a quantum description of the information conservation in the process of black hole evaporation [5–10]. This was done without the recourse to a complete understanding of the quantum dynamics of black holes, which seems to necessarily involve the understanding of quantum gravity.

The origin of the information paradox dates back to decades ago. In 1975, Hawking proposed that the information falling into the black hole would disappear after the evaporation of the black hole [1, 4]. However, this proposed process violates the unitarity, which is one of the foundations of quantum mechanics. According to the principle of unitarity, the evaporation of a black hole from a pure state with zero entropy has to end with the pure-state quantum gas of radiation instead of mixed-state thermal gas which has a large entropy. This argument incorporating the initial and final state behaviors is represented graphically by the Page curve [2]. Many other proposals were suggested to resolve the information paradox. Some representative ones and their pros and cons were discussed in ref. [11]. One approach suggested to include backreaction leading to final pure state. But it appears to imply that either all of the information has been extracted by the time the falling matter crosses the horizon or that information escapes acausally from the black hole [12]. Another proposal suggested information release at the end of black hole evaporation at the Planck scale. But this proposal requires the remaining Planck scale energy to carry off arbitrarily amount of information which would violate the Bekenstein bound [13–15]. A different proposal suggested the Planck scale remanent after the evaporation. But the
remanent is intrinsically unstable [16]. A proposal on including baby universes as a source of information loss was suggested. But later studies showed that wormholes only change the coupling without violation of unitarity [17]. There was also a proposal on a previously unexpected mechanism of information release. But suggestion seems to require the violation of causality in the horizon [18]. In 1999, Parikh and Wilczek proposed to address the information paradox issue by including the higher order non-thermal effect in the radiation to allow information to leak out from the black hole [19]. However, this effect is negligible for massive black holes and not able to compensate for the information loss in this case.

Whether black hole dynamics preserve unitarity remained a conundrum until present. One of the breakthrough ideas was made by the discovery of AdS/CFT correspondence [20]. The duality is a mathematical realization of the proposed idea of the black hole complementarity [21], and provides a strong evidence for the conservation of information as the black hole in the anti-de Sitter space (AdS) can be mapped to the boundary CFT. Therefore, the evaporation of the black hole has a dual unitary description using the boundary CFT. If this argument is true, the evaporation of black holes should roughly follow the Page curve. However, the quest to obtain the Page curve remains unsuccessful until very recently. Apart from that, the unitary process was shown to generate a “firewall” (AMPS firewall) on the black hole horizon which is at odds with the “no drama” principle of the general relativity [21]. For eternal black hole, similar questions on the information paradox can be addressed. For a unitary evolution, the corresponding Page curve is expected to reach a bounded value which is the Bekenstein-Hawking entropy of the black hole. The amount of radiation for a eternal black hole is infinite at the “end stage” or the late times of the evaporation. Thus, a thermal spectrum of radiation would produce an infinite amount of entropy. This is contradictory to the unitarity which dictates the maximal entropy produced by the black hole to be the Bekenstein-Hawking entropy. A resolution to all the issues related to the black hole information paradox has been long-yearned.

The Page curve of Hawking radiation was recently calculated by using the semi-classical method for the two-dimensional black holes in the asymptotically AdS spacetime in the Jackiw-Teitelboim (JT) gravity [6, 7]. Most of the studies on the the black hole information problem have been concentrated on the two dimensional gravity where the systems have more symmetries to admit analytic solutions and are easier to analyse [22–29]. In the two dimensional systems, islands appear at the later stage of the black evaporation, which is in the entanglement wedge of the radiation, such that the Bekenstein bound of the entanglement entropy is preserved. For a review see ref. [7]. However, whether this island construction can be extended to and resolve the information issue of all black hole solutions still remains to be verified. For higher dimensional or “realistic” black holes in four dimensional asymptotic spacetime, the resolution of the information paradox is much less studied due to the difficulty in calculating the entanglement entropy and analysing the dual conformal field theory (CFT). It is argued in [9] that the islands should exist in the higher dimensional black hole spacetimes and the unitary Page curves can also be reproduced if taking the island’s effect into account. Recently, some interesting phenomenological studies of the island structure and the Page curves in four dimensional Schwarzschild and dilaton black hole were performed in ref. [31, 34]. Some other studies of different models in higher
dimensions can be found in refs. [29–38].

Our present understanding of the entropy of quantum systems coupled to gravity does not necessarily requires holography and AdS space [7], it is nevertheless an essential tool in the development of the entropy of gravitational systems. The groundbreaking work of Ryu and Takayanag (RT) using AdS/CFT correspondence connects the entanglement entropy of the boundary region to the area of the minimal surface in the bulk space [39]. Later works generalized the RT surface to the quantum extremal surface, in which the generalized entropy includes all the quantum corrections of the bulk fields [9, 10, 40–43]. It is shown that by applying the extremal surface technique, islands appear at the later stage of black hole evaporation process, and that the entropy of Hawking radiation obeys the Page curve assuming the unitary [7]. Furthermore, the island formula for the fine-grained entropy of the Hawking radiation is proposed to be [10, 23, 43, 44]

\[ S(R) = \min \left\{ \text{ext} \left[ \frac{\text{Area}(\partial I)}{4G_N} + S_{\text{matter}}(R \cup I) \right] \right\} \] (1.1)

where \( R \) is the radiation, \( I \) is the island, and \( S_{\text{matter}} \) is the entropy of quantum fields. It is shown that the island formula can be derived without holography from the Euclidean path integral by using the gravitational replica method. The presence of replica wormholes as the saddle points in the Euclidean path integral leads to the island formula not only for the eternal black holes but also for the evaporating black holes [7, 45, 46].

The black hole information paradox has been addressed mainly in two-dimensional gravity models. It is equally important, if not more, to resolve the paradox in our real universe, which is four-dimensional and reaches Minkowski space asymptotically. In the classical general relativity and cosmology, there are a few important 4D vacuum solutions to Einstein’s theory of relativity that deserve particular attention. In this article, we will address the information paradox issue in the four dimensional charged black hole solution in the asymptotically flat spacetime and study the island structure. In this study, we construct the Page curve for the four dimensional eternal Reissner–Nordström black holes in the asymptotically flat spacetime and show that the entanglement island in this case saves the entropy of the radiation from exploding at the late times. This quantitatively resolves the information paradox for the Reissner–Nordström black hole.

In this work, we will apply the method of quantum extremal surface to study the entropy of Hawking radiation and the corresponding Page curve of the Reissner–Nordström spacetime in four dimensions. The action is given by the Einstein-Maxwell action

\[ I = \frac{1}{16\pi G_N} \int_M d^4x \sqrt{-g} \left( R - \frac{1}{4} F_{\mu \nu} F^{\mu \nu} \right) + I_{\text{matter}}, \] (1.2)

where \( G_N \) is the Newton constant, and \( I_{\text{matter}} \) is the action of the matter fields. If the matter fields are described by the CFT and in the vacuum states, the vacuum solution to the Einstein-Maxwell action will not be affected by the matter fields. It is straightforward to generalize the analysis to gravity with higher curvature terms, but we focus only on the dominant contributions.
The metric of the Reissner–Nordström black holes is given by

\[
ds^2 = -\left(1 - \frac{2M}{r} + \frac{Q^2}{r^2}\right)dt^2 + \left(1 - \frac{2M}{r} + \frac{Q^2}{r^2}\right)^{-1}dr^2 + r^2d\Omega^2,
\]

where we have set the Newton’s constant and the Coulomb constant equal to 1, i.e. \(G_N = K = 1\). In the following, these physical constants can be easily restored if necessary. Reissner–Nordström spacetime is one of the most important vacuum solutions of the Einstein’s field equation representing a charged black hole in the 4D asymptotic Minkowski space. One of the distinctions of the Reissner–Nordström black hole from the Schwarzschild black hole spacetime is the appearance of the two horizons (event horizon and causal horizon) even though the inner causal horizon is believed to be unstable under small perturbations due to the mass inflation phenomenon. The radius of the horizons are given by \(r_\pm = M \pm \sqrt{M^2 - Q^2}\) and the surface gravity at the horizons is given by \(\kappa_\pm = \frac{r_+ - r_-}{2r_\pm}\). The Hawking temperature of the Reissner–Nordström black hole is given by

\[
T_{RN} = \frac{\kappa_+}{2\pi}.
\]

In the present work, we only consider the non-extremal black holes.

This paper is arranged as follows. In section 2, we present an approximate method to compute the entanglement entropy for quantum fields in four dimensions. In section 3, the entropy of Hawking radiation is computed without islands and the corresponding information paradox for the eternal Reissner–Nordström black hole is sharpened. In section 4, we analyze the generalized entropy of Hawking radiation and reproduce the unitary Page curve when taking the effect of islands into account. Based on these results, we also discuss the Page time and scrambling time for the Reissner–Nordström black holes. The discussion and conclusion are presented in the last section.

2 The entanglement entropy: general approach

In the following sections, we carry out the calculation of the entanglement entropy in the four dimensional Reissner–Nordström geometry without/with involving the islands. The entanglement entropy for a general four dimensional spacetime is not known. However, the Hawking radiation observed from a distant observer can be properly described by the s-wave approximation. Therefore, we can apply the analysis in the two dimensional case to obtain the entanglement entropy in the curved four dimensional spacetime under some approximations.

For the one dimensional quantum many-body systems at criticality (i.e. CFT in two-dimensions), it is known that the entanglement entropy ignoring the UV-divergent part (or Plank scale physics) is given as follows,

\[
S_A = \frac{c}{3} \cdot \log(\frac{L}{\pi \epsilon} \sin(\frac{\pi l}{L})) \simeq \frac{c}{3} \cdot \log l,
\]

where \(l\) and \(L\) are the lengths of the subsystem \(A\) and the total system, \(\epsilon\) is the UV cutoff, and \(c\) is the central charge of the CFT. We have assumed that \(l \ll L\) and kept only the finite part.
As is shown by Ryu and Takayanagi, the entanglement entropy in the boundary (d+1)-
dimensional CFT has a dual description in the bulk. It follows a simple area law when
mapped into the bulk, i.e.
\[ S_A = \frac{\mathcal{A}}{4G_{d+2}^N}, \]  
where \( \mathcal{A} \) is the area of the the d-dimensional static minimal surface in the AdS_{d+2}. For the
two-dimensional CFT, it is just the length of the minimal curve in the bulk. This formula
is applied when no island is formed.

For two dimensional systems with multiple disjoint intervals, \( A = \{x \mid x \in [r_1, s_1] \cup [r_2, s_2] \cup ... \cup [r_N, s_N]\} \), the generic formula for the entanglement entropy derived from the
Ryu-Takayanagi formula is given as
\[ S_A = \sum_{i,j} L_{r_j,s_i} - \sum_{i<j} L_{r_j,r_i} - \sum_{i<j} L_{s_j,s_i}. \]  
where \( L_{r_j,s_i} \) is the minimal surface in the bulk with the boundary points \([r_j, s_i]\) and \(G_N\)
is the Newton’s constant in 3 dimensions. Combining Eq. (2.1), Eq. (2.2) and Eq. (2.3)
will allow us to compute the entanglement entropy for disjoint union of intervals. This
general RT formula will be useful when one or more islands appear. Allowing any possible
number or shape of islands also make the analysis extremely tedious. For the simplicity
of the study, we restrict to the case that either has no island or only one island. We will
show that this is sufficient to solve the information problem of the black hole and gives the
sensible Page curve.

With the method to calculate the entropy, we apply the quantum extremal surface
approach with the islands. First, we use the explicit expression for the generalized entropy,
\[ S_{gen} = \frac{\text{Area}(\partial I)}{4G_N} + S_{\text{matter}}(R \cup I), \]  
and then extremize it with respect to time and spacial coordinates of the island. If no
saddle point is found, then we claim that no island will form in that case. Otherwise, we
include the configurations of the islands in the generalized entropy and take the minimal
values of all such saddle points. If the island configuration can resolve the information
paradox, we expect that the entropy at late times reaches a finite value which is bounded
by the Bekenstein-Hawking entropy. Otherwise, the information will not be conserved and
remain to be an conflicting issue of gravity and quantum mechanics.

3 The diverging entanglement entropy without island

In this section, we will calculate the entanglement entropy of the radiation at late times
without considering the contributions of the islands and sharpen the information paradox
for the Reissner–Nordström black holes. In the absence of the island, we have only two
endpoints of the entanglement region of the radiation which are the boundary points of
the region \( R_+ \) at the right and the one on the left \( R_- \) (see Fig. 1).

At the late time of the evaporation process, we refer the entanglement entropy to
Eq. (2.1). If we assume the system is in the pure state at \( t = 0 \), the entanglement entropy
Figure 1. Penrose diagram for the eternal Reissner–Nordström black hole without islands. Hawking radiation is assumed to lie on the region $R_+$ and $R_-$. $b_{\pm}$ are the boundary surfaces of $R_+$ and $R_-$, respectively.

of the radiation is the same as the entanglement entropy of the region $[b_-, b_+]$. Therefore, we have

$$S_R = \frac{c}{3} \log d(b_+, b_-),$$

(3.1)

where $b_+$ and $b_-$ stand for the boundaries of the entanglement regions in the right and the left wedges of the Reissner–Nordström geometry and $d(b_+, b_-)$ is the distance between the points $b_+$ and $b_-$. Here $(t, r) = (t_b, b)$ for $b_+$, and $(t, r) = (-t_b + i\beta/2, b)$ for $b_-$, respectively. Here, $\beta = 2\pi/\kappa_+$ is the inverse of the Hawking temperature and $\kappa_+$ is the surface gravity at the outer horizon.

Though the existence of the inner horizon in the Reissner–Nordström black hole will not admit the Cauchy surface like the case of the Schwarzschild spacetime, the inner horizon in the Reissner–Nordström black hole is unstable under small perturbations [48]. On the other hand, allowing the inner horizon will cause many other issues such as the violation of strong cosmic censorship, therefore, the effect of the inner horizon is ignored. We will see in latter that the assumption is justified. Under this assumption, we refer to the Kruskal-Szekeres-like coordinates in the Reissner–Nordström spacetime which is given by [47]

$$ds^2 = -\frac{r_+ r_-}{r^2 \kappa_+^2} \left( \frac{r_-}{r - r_-} \right)^{\kappa_+ - 1} e^{-2\kappa_+ r} dU dV + r^2 d\Omega_2^2,$$

(3.2)
where we have defined the coordinates as
\[
\begin{align*}
    r_* &= r + \frac{r_+^2}{r_+ - r_-} \log |r - r_+| - \frac{r_-^2}{r_+ - r_-} \log |r - r_-| , \\
    U &= e^{-\kappa_+(t-r_*)} , \quad V = e^{\kappa_+(t+r_*)} .
\end{align*}
\] (3.3)

For simplicity, we denote the conformal factor of the Reissner–Nordström black hole geometry as \( f^2(r) \), i.e.
\[
    f^2(r) = \frac{r_+ r_-}{r^2 \kappa_+^2} \left( \frac{r_-}{r - r_-} \right)^{\frac{\kappa_+}{\kappa_-} - 1} e^{-2\kappa_+ r} .
\] (3.5)

The metric after the conformal map is simply as follows,
\[
    ds^2 = -f^2(r) dU dV + r^2 d\Omega^2 .
\] (3.6)

Following the conformal mapping, the matter part of the entanglement entropy in the Reissner–Nordström geometry is
\[
    S_R = \frac{c}{6} \log \left[ f(b_+)f(b_-) (U(b_-) - U(b_+)) (V(b_+) - V(b_-)) \right] .
\] (3.7)

The total entanglement entropy by applying formula Eq. (2.1) is calculated as
\[
    S = \frac{c}{6} \log \left[ 4 f(b)^2 e^{2\kappa_+ r_*} \cosh^2 \kappa_+ t \right] ,
\] (3.8)

where
\[
    r_*(b) = b + \frac{r_+^2}{r_+ - r_-} \log |b - r_+| - \frac{r_-^2}{r_+ - r_-} \log |b - r_-| .
\] (3.9)

This formula Eq. (3.8) gives the information of the black hole fine-grained entropy as a function of time when no island is considered.

We notice that this entropy blows up as \( t \to \infty \),
\[
    S \sim \frac{c}{6} \log(4 \cosh^2 \kappa_+ t) \sim \frac{c}{3} \kappa_+ t .
\] (3.10)

Therefore, without island the information does not leak out of the black hole and the entanglement entropy increases linearly with time. No Page time shows up in this calculation and the entropy of the radiation will eventually be infinitely larger than the Bekenstein-Hawking entropy of the black hole. Assuming that the eternal black is sustained by feeding it on pure states quanta, the total von Neumann entropy of the black hole does not change and the entanglement entropy of radiation is at most double the Bekenstein-Hawking entropy (left and right regions in the conformal diagram). Therefore, there is clearly a paradox here. We shall see that the island construction will resolve this issue and predict the Page curve for eternal Reissner–Nordström black holes in the next section.
Figure 2. Penrose diagram for the eternal Reissner–Nordström black hole with the assumption of island. The islands extend to the outside of the horizons of the black holes. The boundaries of islands are located at $a_+$ and $a_-$. The points $b_\pm$ are the boundaries of the left and right radiation regions $R_-$ and $R_+$. 

4 The entanglement entropy with island

In this section we calculate the entanglement entropy with a single island. For eternal Reissner–Nordström black hole, we are only interested in the long-time limit behavior of the entanglement entropy, i.e. late time radiation, we consider the case when the boundary $r = b$ of the entanglement region $R$ is far away from the horizon, $b \gg r_h$. In this case, we assume that the s-wave approximation is valid. and use the matter entropy formula for calculating the total entropy.

The expression of the entanglement entropy for the conformal matter is inferred by Eq. (2.3)

$$S_{\text{matter}} = \frac{c}{3} \log \frac{d(a_+,a_-)d(b_+,b_-)d(a_+,b_+)d(a_-,b_-)}{d(a_+,b_-)d(a_-,b_+)}.$$  \hfill (4.1)

Using the Kruskal coordinates given in Sec. 2, the generalized entropy is the semi-classical fine-grained entropy in Eq. (2.3) plus the area of the quantum extremal surface as is given by

$$S_{\text{gen}} = \frac{2\pi a^2}{G_N} + \frac{c}{6} \log \left[ \frac{2^4 f^2(a)f^2(b) e^{2r_+(a)+r_+(b)} \cosh^2(\kappa_+ t_a) \cosh^2(\kappa_+ t_b)}{\cosh(r_+(a) - r_+(b)) - \cosh(\kappa_+(t_a - t_b)) \cosh(\kappa_+(t_a + t_b))} \right],$$  \hfill (4.2)
where \( r_*(a) \) and \( r_*(b) \) are defined in Eq. (3.3) and \( f^2(x) \) is the conformal factor of the metric,

\[
f^2(r) = \frac{r_+ - r_-}{r^2 \kappa_+^2} e^{2 \kappa_+ r}.
\]

(4.3)

and the \( r_*(a) \) is defined to be

\[
r_*(a) = a + \frac{r_+^2}{r_+ - r_-} \log |a - r_+| - \frac{r_-^2}{r_+ - r_-} \log |a - r_-|.
\]

(4.4)

The first term in Eq. 4.2 corresponds to the area of the island, and the second and third term correspond to the entropy of the matter outside the cutoff surface and inside the island \( R \cup I \). To get the entanglement entropy we still need to extremize the formula of the generalized entropy Eq. (4.2) over all possible Cauchy surfaces. However, we can already get some information from this formula. At the first glance, this formula also appears to explode as the time goes to infinity. However, one should keep in mind that we also introduced free parameters into the formula. Once we have extremized Eq. 4.2, we can hope that a bounded answer will show up as time goes to the infinity.

4.1 Early times

This formula is very hard to deal with directly without any approximation made. In the following, we study the early and late times behavior of the island the entropy. The structure of the island can be analysed as follows. At early times, the entanglement entropy of the black hole with the radiation is small and thus the extremal surface has to lie deep inside the black hole if it exists at all. We assume that \( t_a, t_b \ll r_+ \) and we pick the cutting surface far away from the horizon \( b \gg r_+ \). Then the last term in the generalized entropy Eq. (4.2) can be properly ignored and the generalized entropy is approximately as follows,

\[
S_{\text{gen}} \approx \frac{2 \pi a^2}{G_N} + \frac{c}{6} \log \left[ 2^4 f^2(a) f^2(b) e^{2 \kappa_+ (r_*(a) + r_*(b))} \cosh^2(\kappa_+ t_a) \cosh^2(\kappa_+ t_b) \right]
\]

\[
\approx \frac{2 \pi a^2}{G_N} + \frac{c}{3} ( kr_*(a) + \log f(a) ) + \text{functions of } (t_b, r_*(b)) \text{ which will be omitted}
\]

\[
\approx \frac{2 \pi a^2}{G_N} + \frac{c \kappa_+}{3} \left( \frac{r_+^2}{r_+ - r_-} \log |a - r_+| + \left( \frac{r_-^2 + r_+^2}{2r_+^2} - \frac{r_-^2}{r_+ - r_-} \right) \log |a - r_-| - \log a \right).
\]

(4.5)

Extremize this function over \( a \) under the approximation that \( t_a, t_b \ll r_*(b) - r_*(a) \), we find that

\[
a \approx \sqrt{\frac{c}{12 \pi}} \cdot l_P
\]

(4.6)

where \( l_P \) is the Plank length. Naively we get a Plank scale island inside the black hole which can store the minimal amount of information. However, the upper cutoff length of the above approach is far above Plank length and we have thrown away all Plank scale physics. Besides we cannot draw the Cauchy surface into the inner horizon which is not covered by the metric we adopted. This controversy really means that in the regime where
our analysis applies, there does not exist a nonvanishing quantum extremal surface that minimize the generalized entropy. This can be verified by comparing the entropy achieved above with the entropy calculated without island Eq. (3.8),

\[ S = \frac{c}{6} \log \left[ 4f(b)^2e^{2\kappa_+b} \cosh^2 \kappa_+ t \right], \tag{4.7} \]

which should be understood as the limit of Eq. (4.5) for small island radius \( a \).

In the early times, no island is formed and we refer to the discussion with no island in Sec. 3. In this case, the entanglement entropy grows approximately linearly with time as the entangled Hawking radiation enters into the cutoff surface.

### 4.2 Late times

At late times, as more and more radiation enters into the cutoff surface, the fine-grained entropy using the formula Eq. (3.8) becomes less and less accurate. The linear increase of entropy is what should be expected for the coarse-grained entropy, but for the fine-grained entropy such behavior is prohibited by the unitarity. A simple argument was given by D. Page, that at the early stage when the subsystem is substantially smaller than the total system, the entanglement entropy can be approximated by the thermal entropy of the subsystem. Exploiting this argument, we should expect the fine-grained entropy goes linearly with time at the beginning of the radiation. However, at the end of the radiation we can apply this argument again to with the small subsystem being the black hole, and we should expect the linear decrease of the black hole fine-grained entropy. In this section, we will introduce island construction into the discussion and see if implementing one island will resolve the issue in the black hole at late times of the radiation.

We will proceed by assuming \( t_a, t_b \gg b > r_+ \). We first extremize the generalized entropy Eq. (4.2) with respect to time \( t_a \). The time-dependent component of the generalized entropy is given by

\[ S_{\text{gen}} \supset \frac{c}{3} \log \left\{ \cosh \kappa_+ t_a \cosh \kappa_+ t_b \right\} \frac{\cosh \kappa_+(r_+(a) - r_+(b)) - \cosh \kappa_+(t_a - t_b)}{\cosh \kappa_+(r_+(a) - r_+(b)) + \cosh \kappa_+(t_a + t_b)} \right\}. \tag{4.8} \]

Employing the following approximations,

\[ \cosh \kappa_+ t_{a,b} \simeq \frac{1}{2} e^{\kappa_+ a_{a,b}}, \tag{4.9} \]

and

\[ \cosh \kappa_+(t_a + t_b) \gg \cosh \kappa_+(r_+(a) - r_+(b)), \tag{4.10} \]

and we have the following time-dependent entropy expression,

\[ S_{\text{time}} \simeq \frac{c}{3} \log \left\{ \cosh \kappa_+(r_+(a) - r_+(b)) - \cosh \kappa_+(t_a - t_b) \right\}. \tag{4.11} \]

We can readily observe that the maximal value of the \( S_{\text{time}} \) is obtained when \( t_a = t_b \) under the approximations made. When substituting \( t_a = t_b = t \), we notice that the explicit

\footnote{In principle we should also include the absolute value sign inside the logarithm, but since the points \( a \) and \( b \) are on the same Cauchy slice we can ignore the negative value issue.}
time dependence disappears from this equation, which is the early sign that the entropy is bounded!

Now we invoke the above and the following approximations,
\[ \cosh (\kappa_+ (r_+ (a) - r_+ (b))) \simeq \frac{1}{2} e^{\kappa_+ (r_+ (b) - r_+ (a))}, \quad (4.12) \]
and rewrite it in terms of Reissner–Nordström coordinate variables,
\[ \cosh \kappa_+ (r_+ (a) - r_+ (b)) \simeq \frac{1}{2} e^{\kappa_+ (b - a)} \left| \frac{b - r_+}{a - r_+} \right| \frac{\kappa_+ r_+^2}{r_+ - r_-} \left| \frac{b - r_-}{a - r_-} \right|^{- \frac{\kappa_+ r_+^2}{2(r_+ - r_-)}}. \quad (4.13) \]

Applying the above approximations, we have the generalized entropy \( S_{\text{gen}} \) read
\[ S_{\text{gen}} = \frac{2\pi a^2}{G_N} + \frac{c}{6} \log \left[ \frac{2^{\frac{b}{3}} f^2 (a) f^2 (b) e^{\frac{2\kappa_+ (r_+ (a) + r_+ (b))}{\kappa_+ (t_a)}} \cosh^2 (\kappa_+ t_a) \cosh^2 (\kappa_+ t_b)}{\cosh (\kappa_+ (r_+ (a) - r_+ (b))) - \cosh (\kappa_+ (t_a - t_b))} \right] \]
\[ + \frac{c}{3} \log \left[ \frac{\kappa_+ (r_+ (a) - r_+ (b)) + \cosh (\kappa_+ (t_a + t_b))}{\cosh \kappa_+ (r_+ (b) - r_+ (a))} \right] \]
\[ \simeq \frac{2\pi a^2}{G_N} + \frac{c}{6} \log \left[ f^2 (a) f^2 (b) \right] + \frac{c}{3} \log \left[ \frac{1 - 2 e^{-\kappa_+ (r_+ (b) - r_+ (a))}}{1 + e^{\kappa_+ (r_+ (b) - r_+ (a)) / 2t_b}} \right] + \frac{2c}{3} \kappa_+ r_+ (b) \]
\[ \simeq \frac{2\pi a^2}{G_N} + \frac{c}{6} \log \left[ f^2 (a) f^2 (b) \right] + \frac{2c}{3} \kappa_+ r_+ (b) \]
\[ + \frac{c}{3} \left[ -2 e^{-\kappa_+ (r_+ (b) - r_+ (a))} - e^{\kappa_+ (r_+ (b) - r_+ (a)) / 2t_b} \right] \]
\[ \simeq \frac{2\pi a^2}{G_N} + \frac{c}{6} \log \left[ f^2 (a) f^2 (b) \right] + \frac{2c}{3} \kappa_+ r_+ (b) \]
\[ + \frac{c}{3} \left[ -2 e^{-\kappa_+ (b - a)} \left| \frac{a - r_+}{b - r_+} \right| \frac{\kappa_+ r_+^2}{r_+ - r_-} \left| \frac{a - r_-}{b - r_-} \right|^{- \frac{\kappa_+ r_+^2}{2(r_+ - r_-)}} - e^{\kappa_+ (r_+ (b) - r_+ (a)) / 2t_b} \right], \quad (4.14) \]

where in the second approximately equal sign we used the approximation
\[ 2 \cosh (\kappa_+ t_a) \cosh (\kappa_+ t_b) \simeq \cosh (\kappa_+ (t_a + t_b)). \quad (4.15) \]

In the equation after the third approximately equal sign we assumed the first order expansion in the logarithm, and in last line we applied the approximation Eq. (4.13).

We notice that the expression has a weak dependence on the time \( t_b \) as indicated by the last term. However, this term is of higher order and its magnitude decays exponentially as time goes on. Therefore, the exact location of the island depends on the time but its
dependence rapidly dies off and reaches to the asymptotic value. Here, we consider the later stage of the evaporation where the information bound might be broken and ignore the subdominant terms. One of the remarkable differences of this result from the previous ones assuming no island (Eq. (3.8)) is the disappearance of the explicit time dependence at late stage in the generalized entropy. This implied that after extremization, we should get an answer that is independent of the time, which suggests a convergent behavior of the entanglement entropy instead of going linearly with time.

We extremize this result with respect to $a$, and the extremal value of the generalized entropy occurs at

$$a \simeq r_+ + \left[ \frac{G_N c \cdot e^{\kappa_+(r_+-b)}}{12\pi r_+ \sqrt{b-r_+}} \left( \frac{r_+ - r_-}{b - r_-} \right) - \frac{r_+^2}{r_+^2} \right]^2. \quad (4.16)$$

The boundary of the island locates slightly outside the outer horizon and it covers some space near the horizon as shown in Fig. 2. The higher order correction to the location of the island is dependent on the location of the cutoff surface. Suppose that we set the cutoff surface close to the horizon $b \rightarrow r_+$ (though in a strict sense the validity of the result in this extreme case is questionable), this second order term vanishes and the location of the island is precisely at the horizon up to the even higher order. Therefore, this higher order term can be understood partially as the artifact of the arbitrariness of the cutoff surface.

This location of the island results in the entanglement entropy to be as follows,

$$S_{\text{entanglement}} \simeq \frac{2\pi r_+^2}{G_N} + \frac{c}{3} \log \left[ \frac{r_-}{b \cdot \kappa_+^2} \left( \frac{r_-^2}{(r_+ - r_-)(b - r_-)} \right)^{\frac{\kappa_+ - \kappa_-}{b \cdot \kappa_+} e^{2\kappa_+(b-r_+)}} \right] + \text{small}. \quad (4.17)$$

The first dominant term of this equation is the Bekenstein-Hawking entropy which naturally comes out from the island construction. The maximal entropy of the radiation is the black hole thermodynamic entropy in the $t \rightarrow \infty$ limit, or equivalently when infinite amount of radiation has been generated by the black hole. Combining the results of the early times and the late times, we have roughly the Page curve which is shown in Fig. 3. It should be noted that the higher order terms in $cG_N/r_h^2$ are negligible compared to $t_{\text{Page}}$ or $S_{\text{BH}}$ and are ignored. This shows the preservation of the information and unitarity in the evolution of black holes and resolves the potential information paradox issue since the entanglement entropy is bounded by the Bekenstein-Hawking entropy of the Reissner–Nordström black hole which is finite. This is in contrast to the Hawking’s original argument of infinite radiation entropy at the end stage of the eternal black hole, which directly violates the unitarity and information conservation. Similarly, the AMPS firewall paradox can also be avoided in the Reissner–Nordström black hole due to the appearance of the island in the later stage of the black evaporation. The appearance of the islands renders some degrees of freedom of the black hole interior to be inside the entanglement wedge of the radiation. Therefore, not all the degrees of freedom inside the black hole should be counted as the black hole degrees of freedom but only the ones in its entanglement wedge. The assumption
Figure 3. The Page curve for the eternal Reissner–Nordström black hole with the assumption that the higher order terms in $c G_N/r_+^2$ are ignored. The orange dashed line shows the result without islands. The solid line represents the quantitative result with island.

on the degrees of freedom of black holes implicitly made in the AMPS proposal should be released and no firewall near the black hole horizon is expected.

What we discussed above is the non-extremal black hole. For the extremal spacetime, its local geometry is near the horizon is identical to that of an $AdS_2 \times S_2$, and thus its low energy dynamics can be described by the Jackiw-Teitelboim theory whose properties are known. In the theory of the J-T gravity, similar calculations can be conducted to study the island structure and the conclusions are similar to what we have found in the above discussions. This scenario is discussed in ref. [6] and we will not elaborate here.

4.3 Page time and scrambling time

The time when the entropy of the radiation reaches the maximum is the called the Page time. In an evaporating black hole, it is the time after which the entropy of the radiation starts to decline and is around when the black hole is half of its initial mass. For an eternal black hole, its entropy will be a constant after the Page time.

The Page time for the Reissner–Nordström black hole can be inferred from the expression of the entropy without island [Eq. (3.8)]. It is approximately the time when the entropy reaches its maximal value. From this argument, we can calculate the Page time to be as follows,

$$t_{\text{Page}} \sim 6\pi r_+^2/(c \cdot \kappa G_N) = \frac{12\pi r_+^4}{c \cdot G_N (r_+ - r_-)} = \frac{3}{2\pi c} \frac{S_{\text{BH}}}{TH},$$

(4.18)

here $S_{\text{BH}}$ is the Bekenstein-Hawking entropy for the pair of black holes, which is double the entropy of a single black hole. This Page time is comparable to the black hole half life time.
According to the Hayden-Preskill protocol, the scrambling time dictates how long the dictionary thrown into a black hole can be decoded from the out Hawking radiation [50]. In the language of the entanglement wedge construction, the scrambling time corresponds to the time when the information enters into the island. After that we assume that the information is retrievable in some ways through deciphering the radiation. The location of the island is related to the scrambling time in the way such that a light ray sent off from the cutoff surface a scrambling time ago intersects with the boundary of the island. In the case of eternal black hole, the location of the island is fixed in the asymptotic future. Therefore, the scrambling time is essentially the boundary time that the null rays takes to reach the island.

Suppose we send a message from the cutoff surface at $r = b$ to the black hole, the time it takes to reach the $r = a$ is given as follows,

$$\Delta t = b - a + \frac{r_+^2}{r_+ - r_-} \log \frac{a - r_+}{b - r_-} - \frac{r_-^2}{r_+ - r_-} \log \frac{a - r_-}{b - r_+}. \quad (4.19)$$

Given that the island is located at

$$a \simeq r_+ + \left[ \frac{G_N c \cdot e^{\kappa_+ (r_+ - b)}}{12 \pi r_+ \sqrt{b - r_+}} \left( \frac{r_+ - r_-}{b - r_-} \right)^2 \right]^2, \quad (4.20)$$

we can calculate the time the information takes to enter the island. Once the information is in the entanglement wedge, we assume that the information is in principle retrievable. Therefore, using the location of the islands we have the scrambling time as follows,

$$t_{\text{scramble}} \simeq \frac{2r_+^2}{r_+ - r_-} \log \frac{r_+^2}{G_N} + \text{small} \simeq \frac{1}{2\pi T_{RN}} \log S_{BH}. \quad (4.21)$$

The leading order is consistent with the result derived in refs. [49, 50], which is negligible compared to the Page time. This result from the Reissner–Nordström black hole corroborates the argument of the fast-scrambling of information of the black holes.

5 Discussion

Though the real black hole information paradox is phrased in the context of an evaporating black hole, the paradox and the physics can be equally addressed in the context of an eternal black hole which has all the essence of the problem. For an evaporating black hole, the amount of radiation is bounded. The black hole disappear and the fine-grained entropy has to be zero at the end of the evaporation process. This is at odds with the thermal Hawking radiation. For an eternal black hole, the amount of radiation is infinite at the “end stage” of the evaporation and the black hole is in the same initial condition. Then the thermal radiation should produce infinite amount of entropy for the radiation and that is contradictory to the unitarity which dictates the maximal entropy produced by the black hole to be the black hole Bekenstein-Hawking entropy. The two versions of the paradox is essentially the same and can be addressed in either context. The AMPS
firewall problem can similarly be applied to the eternal black hole scenario, which predicts a constant firewall at the horizon [6, 21]. However, this melodrama can be avoided from the argument of ER=EPR [51].

In summary, in this study we investigated the information problem of one of most well-known solutions to Einstein’s equation, the 4-dimensional Reissner–Nordström space-time. In the initial period, no island is formed. This is due to the fact that the quantum entanglement entropy for the gravitational system is approximately the minimal of the two components in many circumstances, one is the area of the island and the other is the radiation in its entanglement wedge. At the early stage, not enough radiation has been produced and thus the contribution to the entanglement entropy comes mainly from the radiation and no island is needed. At the late time stage, the radiation becomes the predominant term and the entanglement is mainly from the area of the island, which lies very close to the horizon. Using the configuration of the island, we derived the scrambling time that is consistent with that given by Hayden-Preskill protocol and the Page time.

However, we should note that in our construction we only considered the case with zero or one island. In general any patterns of island formation is possible. In our Page curve a sharp turning point at the Page time appears, multiple islands around the Page time will presumably soften the edge of the Page curve. Besides, from the configuration of islands we have answered the question if black hole information is conserved in the 4-dimensional Reissner–Nordström background. However, the possible dynamics describing how the information leaks out into the radiation zone is still lacking. One tentative argument is given by the ER=EPR to explain the information leakage [51], which can also be suggested from the entanglement wedge, but a concrete mathematical framework at the level of quantum states is yet to be established.

Acknowledgments
