Abstract. For High frequency BL Lac objects (HBLs) like H1426+428, a significant fraction of their TeV gamma-rays emitted are likely to be absorbed in interactions with the diffuse IR background, yielding $e^\pm$ pairs. The resulting $e^\pm$ pairs generate one hitherto undiscovered GeV emission by inverse Compton scattering with the cosmic microwave background photons (CMBPs). We study such emission by taking the 1998-2000 CAT data, the reanalyzed 1999 & 2000 HEGRA data and the corresponding intrinsic spectra proposed by Aharonian et al. (2003a). We numerically calculate the scattered photon spectra for different intergalactic magnetic field (IGMF) strengths. If the IGMF is about $10^{-15}$G or weaker, there comes very strong GeV emission, whose flux is far above the detection sensitivity of the upcoming satellite GLAST! Considered its relatively high redshift ($z = 0.129$), the detected GeV emission in turn provides us a valuable chance to calibrate the poor known spectral energy distribution of the intergalactic infrared background, or provides us some reliable constraints on the poorly known IGMF strength.

Key words. BL Lacertae objects: general — BL Lacertae objects: individual (H1426+428) — diffuse radiation — gamma rays: theory — magnetic fields

1. Introduction

Several High frequency BL Lac objects (HBLs) such as Mkn501, Mkn421, PKS 2155-304, 1ES 2344+514, H1426+428 and 1ES1959+650 are of great interest, since they emit TeV photons (Catanese & Weekes 1999; Aharonian et al. 1999, 2002a; Horns 2002). As early as in 1960s, it was pointed out that the observed high energy gamma photon spectra from TeV sources might be significantly modified—as the original high energy gamma-rays satisfying $E_{\gamma}E_B > 2(m_e c^2)^2$ (where $E_{\gamma}$ is the energy of the seed high energy gamma-ray, $E_B$ is the infrared–UV background photon) travel through the intergalactic infrared–UV background, a significant fraction of them will be absorbed, leading to $e^\pm$ pairs (Nikishov 1962; Gould & Schrédèr 1965; see also Stecker, de Jager & Salamon 1992). If the optical depth to TeV photons is evaluated, the intrinsic spectrum can be derived. Such calculations were firstly made for Mkn501 (during the 1997 flaring activity), and then for H1426+428, indicating that their intrinsic high-energy spectra have broad, flat peaks which are much higher than the observed one in the $\sim 5 - 10$ TeV range (e.g. Konopelko et al. 1999; Aharonian, Timokhin & Plyasheshnikov 2002; de Jager & Stecker 2002; Aharonian et al. 2003a). Very recently, Dai et al. (2002) have suggested that inverse Compton (IC) scattering of the resulting $e^\pm$ pairs against the cosmic microwave background photons (CMBPs) may produce a new GeV emission component in TeV blazars.\textsuperscript{1} As an illustration, they have calculated the well-studied blazar Mkn501, and obtained strong GeV emission, as long as the intergalactic magnetic field (IGMF) is weak enough.

In this paper, we turn to investigate another important extragalactic object, H1426+428, which has been detected by Remillard et al. (1989) firstly. With the relatively high redshift $z = 0.129$, the optical depth exceeds

\textsuperscript{1} For Gamma-ray bursts, such Compton scattering leads to an observable, delayed MeV-GeV emission component. In fact, there are more than six events have been detected, the well known one is the GRB 940217, whose delayed MeV–GeV emission lasts for $\sim 5000s$ (Hurley et al. 1994). If the model proposed by Plaga (1995) and Cheng & Cheng (1996) (see also Dai & Lu 2002; Wang et al. 2003) is correct, the intergalactic magnetic field is $\approx 10^{-20}$G (For GRB 940217, the redshift is unavailable. But with the empirical relation established based on several GRBs with known redshifts, a rough estimate suggests its redshift is $\sim 0.68$ (Fenimore & Rumirez-Ruiz 2000).

On the other hand, the typical energy of the observed delayed photons is $50\text{MeV}$, which implies the typical energy for the high energy seed photons $E_{\gamma} \approx 0.3$ TeV. Substituting these two estimates into equation (3), we have $B_{IG} \sim 10^{-20}$G.)
unity for energies of \(\sim 300\,\text{GeV}\) (e.g. de Jager & Stecker 2002). Any detection of a signal at TeV energies translates directly into a high luminosity of the source. The detection and spectral measurement of H1426+428 by the CAT, and VERITAS groups (Djannati-Ataï et al. 2002; Petry et al. 2002) indicate a steep spectrum between 250 GeV and 1 TeV, whereas at higher energies, detections have been reported by the HEGRA group based upon observations carried out in 1999 and 2000 (Aharonian et al. 2002b). Here, following Dai et al. (2002), we study such hitherto undiscovered GeV emission by taking the 1998-2000 CAT data (Djannati-Ataï et al. 2002), the reanalyzed 1999 & 2000 HEGRA data as well as the derived intrinsic spectra proposed by Aharonian et al. (2003a).

The predicted GeV emission is sensitive to IGMF (Dai et al. 2002). If the IGMF is stronger than \(10^{-12}\,\text{G}\), the formation of a very extended electron/positron Halo (\(R \sim 10\,\text{Mpc}\) for the primary photons with a typical energy \(\sim 1\,\text{TeV}\)) is unavoidable (Aharonian, Coppi & Völk 1994), and its emission is nearly isotropic. If this is the case, the GeV emission predicted below will be significantly lowered. However, the strength of IGMF has not been determined so far. Faraday rotation measures imply a correction of \(\sim 1\,\text{TeV}\) travel toward the observer, a significant lowering. However, in the present case, for the (loc) denote the parameters measured in the observer and source frames respectively. If a primary photon with energy \(E'_{\gamma}\) has been absorbed, the resulting \(e^{\pm}\) pairs have Lorentz factors \(\gamma' \sim (E'_{\gamma}/(2m_e c^2))^2 \approx 10^5 E'_{\gamma}/1\,\text{TeV}\), where \(m_e\) is the electron mass. Such ultra-relativistic \(e^{\pm}\) pairs will subsequently Compton scatter on the ambient CMBPs, and boost them to an average value \(\sim 2.7kT\) \(\sim 63(1+z)(E'_{\gamma}/1\,\text{TeV})^2\,\text{GeV}\), where \(kT = \gamma'\). This is the mean energy of the CMB photons with \(T \sim 2.73(1+z)\,\text{K}\) and \(k\) is the Boltzmann constant.

Since the emission of blazars is jet-like rather than isotropic, so do the scattered CMBPs. Thus it is necessary to investigate whether significant part of them has been scattered out of the line of sight (the “escaping” effect), or not. For the IC- scattered CMBPs, which move nearly along the path of the ultra-relativistic electrons and the deflection angle is \(\sim 1/\gamma\), much less than the typical open angles of blazars. On the other hand, the recoiling of the seed electrons is small, too. It is easy to show that for one scattering, the deflection angle is \(< \gamma/\sqrt{m_e c^2}\). For a seed electron scattering N times, its final deflection angle can be estimated by \(\theta_{\text{D}} \sim \sqrt{N}\). Typically, for the IC scattering considered in this paper, \(N \sim 1000\), which implies \(\theta_{\text{D}} \sim 10^{-7}\). Therefore, the “escaping” effect can be ignored.

2.1. The GeV emission duration

As shown in Dai et al. (2002), there are four timescales involved in the emission process: The first is \(t_{\text{var,obs}}\), the observed variability time of the source emission, which has been mentioned earlier.

The second is the well-known angular spreading time

\[
\Delta t_{\text{A,obs}} \approx (1+z)\frac{R_{\text{pair}}}{2\gamma' c^2} = 960(1+z)(\frac{\gamma' m_e}{10^6})^2(\frac{n_{\text{HR}}}{0.1\,\text{cm}^{-3}})^{-1}\,\text{s},
\]

where \(R_{\text{pair}} = (0.26\sigma_T n_{\text{HR}})^{-1} \approx 5.8 \times 10^{25}(\frac{n_{\text{HR}}}{0.1\,\text{cm}^{-3}})\,\text{cm}^{-3}\) is the typical pair-production distance, \(\sigma_T\) is the Thomson cross section, and \(n_{\text{HR}} \approx 0.1\,\text{cm}^{-3}\) is the intergalactic infrared photon number density (Dai & Lu 2002; Dai et al. 2002; Wang et al. 2003).

The third is the IC cooling timescale. In the absence of any IGMF, the IC cooling timescale in the observer frame would be (Dai et al. 2002)

\[
\Delta t_{\text{IC,obs}} \approx (1+z)t_{\text{IC,loc}}/(2\gamma'_c) = 38(1+z)^{-3}(\frac{\gamma' m_e}{10^6})^{-3}\,\text{s},
\]

\(t_{\text{IC,loc}}\), the IC cooling time scale measured in the source frame is estimated by \(t_{\text{IC,loc}} = 3m_e c^2/(4\gamma'_c\sigma_T u_{\text{emb}}) = 7.7 \times 10^{13}(1+z)^{-4}(\gamma' m_e/10^6)^{-1}\,\text{s}\), where \(u_{\text{emb}} \sim a T^4\) is the CMB energy density, and \(a\) is the radiation constant.

The fourth is the magnetic deflection time, which appears in the presence of IGMS. The additional emission time due to magnetic deflection is (Plaga 1995; Dai et al. 2002)

\[
\Delta t_{\text{B,obs}} \approx (1/2)(1+z)t_{\text{IC,loc}}\theta_B^2
\]

relatively high red-shift of H1426+428, \(z = 0.129\), the red-shift correction must be taken into account.
\[
\gamma_{e,c} = 0.59 \left( \frac{t_{\text{var,obs}}}{1 \text{ day}} \right)^{-1/5} \left( \frac{B_{\text{IG}}}{10^{-20} \text{G}} \right)^{2/5} (1 + z)^{-11/5} \text{ s}.
\]

For the ultra-relativistic seed electrons with the distribution \(dN_{e}/d\gamma_{e}\), the time-averaged scattered photon spectrum is given by (Blumenthal & Gould 1970; also see Dai \\& Lu 2002; Dai et al. 2002)

\[
\frac{dN_{\gamma}}{dE_{\gamma}} \approx 10^{0.79046 - 3.31624x + 1.15145x^2 - 0.79715x^3} \times \left( \frac{E_{\gamma}}{0.1 \text{TeV}} \right)^{-3/2},
\]

where \(D_L\) is the luminosity distance to the source, \(E_{\gamma}^{\prime}\) is the externally scattered photon energy, \(t\) is the time measured in the local rest frame, and (Blumenthal \\& Gould 1970)

\[
\frac{dN_{\gamma_{i,c}}}{dE_{\gamma}^{\prime}} = \int \frac{dN_{e}}{d\gamma_{e}} \left( \frac{dN_{e}}{d\gamma_{e}} \right) dtd\gamma_{e},
\]

is the spectrum of photons scattered (using the Tompson cross-section formula) by an electron with Lorentz factor of \(\gamma_e\) from a segment of the CMB gas of differential number density (Blumenthal \\& Gould 1970)

\[
n(\epsilon) = [\pi^2 (\hbar c)^3]^{-1} [\epsilon^2 / (\epsilon^3 / kT - 1)].
\]

The integration for variable \(\gamma_{e}\) ranges from \(\gamma_{e,0}\) to \(\gamma_{e}^{\prime} - \gamma_{e}^{\prime} = 10^{0.79046 - 3.31624x + 1.15145x^2 - 0.79715x^3} \times \left( \frac{E_{\gamma}}{0.1 \text{TeV}} \right)^{-3/2}.
\]

Dai \\& Lu (2002) simply replace \(t_{\text{var,obs}}\), and assume the seed electrons have a distribution \(\propto \gamma_{e}^{-3}\). With these simplifications, they have shown that in the Thomson limit, the scattered photon spectrum \(\propto E_{\gamma}^{-(1 + z)/2}\) for \(\Delta t_{\text{B,obs}}(\gamma_e) < t_{\text{var,obs}}\) and \(\propto E_{\gamma}^{-2(1 - z)/3}\) for \(\Delta t_{\text{B,obs}}(\gamma_e) > t_{\text{var,obs}}\). Instead of taking such a simple estimate, below we make a detailed numerical calculation: the integration for variable \(t\) ranges from 0 to 7.7 \times 10^{13} (1 + z)^{-4} (\gamma_{e,c}/10^6)^{-1} \text{ s}.

### 3. Numerical result

In our calculation, the original seed electron energy spectrum is derived as follows: we simply apply a polynomial fit to the local highly absorbed photon spectrum: Setting \(x = \log(E_{\gamma}/1.0 \text{TeV})\), we have

\[
\frac{dN_{\gamma}}{dE_{\gamma}} \approx 5.8 \times 10^{3.8} \left( \frac{E_{\gamma}}{0.1 \text{TeV}} \right)^{-3/2},
\]

which in units of \(4\pi D_L^2 10^{-12} \text{ph cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}\). The local intrinsic photon spectra \(dN_{\gamma_{i,c}}^i/dE_{\gamma}^{i}\) can be approximated as follows (Aharonian et al. 2003a):

\[
\frac{dN_{\gamma_{i,c}}}{dE_{\gamma}^{i}} \approx 6.5 \times 10^{3.8} \left( \frac{E_{\gamma}}{0.1 \text{TeV}} \right)^{-2},
\]

where the superscript \(i = a, b, c\) represent the correction models proposed by Primack et al. (2001), Aharonian et al. (2003a) and Malkan \\& Stecker (2001) respectively. Since \(E_{\gamma} \approx 1(\gamma_e/10^6) \text{ TeV}\), we have (including positrons)

\[
\frac{dN_{\gamma}}{d\gamma_{e}} \approx 2 \times 10^{-6} \left( \frac{dN_{\gamma}^{a,b,c}}{dE_{\gamma}^{i}} \right) \frac{dN_{\gamma}^{i}}{dE_{\gamma}^{i}}.
\]

Now we can calculate the spectra of the scattered CMBPs with equations (5)-(12). Please note that the \(\epsilon, E_{\gamma}^{i}\) in equations (6), (7) are all measured in the local frame rather than by the observer.

The numerical result has been shown in Figure 1. As long as the IGMF strength is weak enough, there is the very strong GeV emission (although it is intrinsic spectrum-dependent), whose flux is far above the thick dashed line, the GLAST sensitivity computed for an exposure time of 2 days. Just as shown in figure 1, the inferred intrinsic spectra is most sensitive to the characteristics of the extragalactic background light. As a consequence, different correction models lead to much different intrinsic spectra, so does the accompanying GeV emission, and thus the detection of such emission may in turn provide us a valuable chance to test those IR background absorption models.
so, as shown in Figure 1, at a first glance, the SSC component is likely far below than the externally scattered photon flux.

4. Conclusions

The HBLs H1426+428 is distinguished by its relatively high redshift as well as its strong TeV energy emission. In this Letter, with the recently observed data as well as the derived intrinsic spectrum, we have studied the possible accompanying GeV emission, which is due to the IC scattering of CMBPs by the $e^\pm$ pairs produced in interactions of high energy photons with the cosmic infrared-UV background photons. If the IGMF is weak enough, there is very strong hitherto undiscovered GeV-TeV emission, whose flux is far above or at least comparable with that of the well-studied HBLs Mkn501 (Dai et al. 2002). With the upcoming satellite GLAST, planned for launch in 2005, it is easy for us to detect such emission directly. We also noted that the shape of the inferred source spectra is most sensitive to the characteristics of the extragalactic background light. A different correction model leads to a different intrinsic spectrum, so does the accompanying GeV emission (see figure 1 for detail). Thus the detection of such emission may in turn provide us a valuable chance to test those IR background absorption models.

In Aharonian et al. (2003b), the detection of TeV $\gamma-$rays from the BL Lac 1ES1959+650 has been reported. 1ES1959+650 is located at a redshift of $z = 0.047$, providing an intermediate distance between the nearby blazars Mkn421 and Mkn501, and the much more distant object H1426+428. Without doubt, for such a source, the observed TeV emission has been absorbed significantly by the infrared-UV background photons, and thus a strong GeV emission is expected, as long as the IGMF is weak enough.
