High-resolution neutron inelastic scattering experiments in applied magnetic fields have been performed on La$_{1.895}$Sr$_{0.105}$CuO$_4$ (LSCO). In zero field, the temperature dependence of the low-energy peak intensity at the incommensurate momentum-transfer $Q_{IC} = (0.5, 0.5 \pm \delta, 0)$ exhibits an anomaly at the superconducting $T_c$ which broadens and shifts to lower temperature upon the application of a magnetic field along the $c$-axis. A field-induced enhancement of the spectral weight is observed, but only at finite energy transfers and in an intermediate temperature range. These observations establish the opening of a strongly downward renormalized spin gap in the underdoped regime of LSCO. This behavior contrasts with the observed doping dependence of most electronic energy features.

In studies of high-temperature superconductors (HTSC), one central challenge is to explain the evolution from an antiferromagnetic (AF) Mott insulator to a metallic superconductor upon doping. For example, the intimate interplay between magnetism and superconductivity has been revealed in momentum resolved inelastic neutron scattering (INS) experiments on La$_{2-x}$Sr$_x$CuO$_4$ (LSCO)\(^1\) and YBa$_2$Cu$_3$O$_{6+x}$ (YBCO)\(^6\) that showed the opening of a spin gap (SG) $\Delta_{sg}$ at the superconducting (SC) critical temperature ($T_c$). In contrast to the single-particle SC gap probed by, e.g., angle-resolved photoemission spectroscopy (ARPES)\(^8\), the SG scales with $T_c$ in the overdoped to slightly underdoped regime. The situation is more complicated in more underdoped samples. For instance, in YBCO the ratio $\Delta_{sg}/(k_B T_c)$ decreases with strong underdoping\(^11\) while for underdoped LSCO ($x < 0.12$) the changes are even more dramatic, since no direct neutron scattering evidence for a SG has been reported so far\(^12\). This latter fact would seem to indicate that the underdoped regime of LSCO cannot be described in terms of a homogeneous electronic liquid and more exotic scenarios have been suggested, such as the formation of dynamical stripes \(^13\) or presence of a $d$-density-wave (DDW) order\(^14\). Further insight into the interplay between magnetism and superconductivity in LSCO has been revealed in a number of studies of the effects of an applied magnetic field, which at optimal doping enhances the low-energy magnetic fluctuations and at underdoping induces static antiferromagnetism\(^15\) or presence of a density wave (DDW) order\(^14\).

In this paper, based on high-resolution INS data as a function of energy $\hbar \omega$, magnetic field $H$ and temperature $T$, we identify similarities and differences between the magnetic response in the underdoped and optimal doped regimes of LSCO. Our main result is the observation of a dramatic field induced enhancement of the response at low energies and the identification, below $T_c$, of a SG in the underdoped regime ($x = 0.105$), whose characteristic energy is strongly renormalized relative to that measured at optimal doping. We also show that this behavior is not specific to LSCO but corresponds to what is observed in YBCO. Unlike at optimal doping, the opening of the $x = 0.105$ SG is incomplete all the way down to the lowest achievable temperature.

Our experiments have been performed on a large cylindrical single crystal of La$_{2-x}$Sr$_x$CuO$_4$ ($m \sim 3.86$ g, $x = 0.105$) grown by the traveling solvent floating zone (TSFZ) method\(^18\). The SC volume fraction was estimated from measurements of the specific heat $C$. At $T_c = 30$ K, we observed a jump of $\Delta C/T_c = 3$ mJ/(K$^2$mol). Below $T_c$ the electronic contribution was estimated to be $C_{el}/T = \gamma_{el} = 0.5$ mJ/(K$^2$mol) while in the normal state we found $C_{el}/T = \gamma_{el} = 5.5$ mJ/(K$^2$mol). This indicates that the SC volume fraction $1 - \gamma_{el}/\gamma_{el}$ is larger than 90%. Together with a sharp SC transition ($\Delta T_c = 1.5$ K), this demonstrates the high quality of the crystal. The structural transition from the high-temperature tetragonal to the low-temperature orthorhombic phase occurs at 290 K, which confirms $x = 0.105 \pm 0.005$. The magnetic response is peaked in the reciprocal space at the incommensurate wave vector $Q_{IC} = (0.5 \pm \delta, 0.5, 0), (0.5, 0.5 \pm \delta, 0)$ (in tetragonal units...
of $2\pi/a = 1.65 \text{ Å}^{-1}$ used throughout this paper). The value $\delta = 0.097 \pm 0.005$ is in line with a Sr concentration of $x = 0.105 \pm 0.005$ [19]. The sample has been characterized by magnetization and ac-susceptibility measurements in magnetic fields $H$ up to 8 T along the crystallographic $c$ axis [20], as well as small-angle neutron scattering (SANS) and $\mu$SR [21]. All measurements indicate that in the underdoped regime of LSCO, the vortex liquid phase dominates the magnetic phase diagram, while a quasi-long-range ordered vortex lattice can only be observed at low fields/temperatures [21]. This contrasts with the well-ordered vortex lattice observed at all fields in the low-temperature regime of optimally doped LSCO [22]. The melting line of the vortex lattice is shown in Fig. 1a.

INS measurements of the spin excitations were performed on the cold neutron spectrometer IN14 at the Institut Laue Langevin, Grenoble, France. We used a vertically curved graphite monochromator and a horizontally curved graphite analyzer with fixed final energy $E_f$ in the range $3.5 - 5 \text{ meV}$ that gave an energy resolution of about $60 - 150 \mu\text{eV}$. A cooled Beryllium-filter removed higher-order contamination from the scattered beam. The sample was cut into two pieces which were coaligned within less than a degree and mounted in a 15 T vertical cryomagnet such that momentum transfers $Q = (Q_h, Q_k, 0)$ were accessible. All measurements were performed after field cooling from above $T_c$. With a similar setup the field dependence of the elastic signal at the incommensurate wave vectors was measured on the FLEX spectrometer at Hahn-Meitner Institute.

In Fig. 1a, we show the effect of $H$ on the $T$ dependence of the intensity at $Q_{IC}$ with an energy transfer of $\hbar \omega = 1 \text{ meV}$. These data demonstrate that the intensity is enhanced by application of $H = 10 \text{ T}$ in an intermediate temperature range $10 \text{ K} < T < T_c$, corresponding roughly to the liquid region of the vortex phase diagram, see Fig. 1a. A similar behavior was previously reported for LSCO samples close to optimal doping [4, 16]. This was interpreted in terms of induced excitations inside the vortex core [16]. Remarkably, the elastic response at $Q = 1 \text{ meV}$ that gave an energy resolution of $0.005 \text{ K}$ exhibits a field dependence at $23 \text{ K}$ that is well fitted by the equation $I \sim (H/H_{c2}) \ln(H_{c2}/H)$ predicted by Demler et al. [15].

Next, we plot in Fig. 2 the $H$ dependence of the normalized intensity at $Q_{IC}$. The elastic magnetic signal at $T = 2 \text{ K}$ exhibits a large enhancement in agreement with previous reports on samples of similar doping levels [17], and is well fitted by the equation $I \sim (H/H_{c2}) \ln(H_{c2}/H)$ predicted by Demler et al. [15]. Remarkably, the inelastic response at $T = 23 \text{ K}$ exhibits a field dependence at low energy transfers similar to the elastic signal. The dependence on $\hbar \omega$ and $Q$ of the intensity, taken at dif-

FIG. 1: (a) Phase diagram of underdoped LSCO ($x = 0.105$) as a function of a magnetic field $H$ and temperature $T$ [20]. Full circles are the measured values for the melting line of the vortex lattice [20]. The straight line is the position of $T_c$ as a function of $H$. The dashed arrows indicate the $T$ and $H$ scans that are described in this paper. (b) Two $T$ scans at $Q_{IC}$ and $\hbar \omega = 1 \text{ meV}$ transfer. Open triangles (filled squares) denote the measured intensity at $H = 10 \text{ T}$ ($H = 0 \text{ T}$), solid lines are guides to the eye.

FIG. 2: Magnetic field dependence of the response at $Q_{IC}$ for LSCO ($x = 0.105$). (a) Elastic response with $T = 2 \text{ K}$. The solid line is a theoretical prediction [15]. (b) Inelastic response with $T = 22.3 \text{ K}$, solid lines are guides to the eye.
FIG. 3: Energy and Q dependence of magnetic scattering from LSCO (x = 0.105). Energy scans are taken at QIC: (a) Comparison of the response in the SC phase with that of the normal state in zero field. (c) Effect of a 10 T field at T = 22.3 K. Q scans through QIC: (b) Comparison of the response in the SC phase with that of the normal state using H = 0.5 meV. (d) The effect of a 10 T field at 22.3 K, hω = 0.3 meV, E_f = 3.5 meV. In this configuration the resolution (HWHM) was 0.03 meV. The data have been background subtracted and lines are guide to the eye.

Different temperatures and fields, is shown in Fig. 3. In Fig. 3a, the intensity at QIC, and at H = 0 T shows a smooth dependence on hω above T_c. At T = 2 K, an anomaly is exhibited at hω = 1.5 meV below which intensity is reduced relative to that in the normal state. Figure 3b shows the effect of cooling through T_c in the Q scan through QIC at H = 0 T and with hω = 0.5 meV. Cooling from 33.5 K to 2 K results in a two-fold reduction of the intensity at QIC. Figures 3c and 3d show the change in the dependence on hω and Q of the intensity at fixed T = 22.3 K upon applying H = 10 T, respectively. The effect of the applied field, Fig. 3c, is to remove the zero-field anomaly at hω = 1.5 meV, and is similar to the effect of raising the temperature above T_c, Fig. 3b. Note that here the magnetic-field-induced redistribution of spectral weight is limited to frequencies smaller than 1.5 meV.

To better appreciate the features of the excitation spectrum described above, a comparison with the SG signatures observed in optimally doped LSCO is relevant. (i) Although the details vary from experiment to experiment [4, 16, 24], magnetic field-induced excitations for hω < ∆_sg and T < T_c remain a common observation. (ii) For hω < ∆_sg, beside the suppression of intensity at low temperatures, an anomaly was reported at T_c that marks the closing of the spin gap as the temperature crosses T_c [25]. (iii) A strong suppression of the intensity below hω ≈ ∆_sg is observed in the SC state but not in the normal state [26]. In our underdoped LSCO sample, we infer from Figs. 1b and 3 similar spin gap features as in optimally doped LSCO. (i) An applied magnetic field acts to redistribute the spectral weight for 10 K < T < T_c at hω < 1.5 meV (Fig. 1b and 3b). (ii) There is the cusp-like anomaly at T_c scanning the temperature for fixed energy below 1.5 meV. (iii) Energy scans reveal an anomaly at hω = 1.5 meV which disappears in the normal state. The field effect (i) alone provides compelling evidence for a spin gap at 1.5 meV. This is further supported by the cusp at T_c (ii), and consistent with the energy dependence (iii). We also find that the intensity at QIC displays the same functional dependence as that reported near optimal doping [27] as a function of T > T_c or hω > 1.5 meV.

We plot in Fig. 4b the dependence of the SG on T_c for LSCO and YBCO samples. Vertical and horizontal axes have been normalized by the values of the SG critical temperature at optimal doping, respectively. The ratio ∆_sg/(k_B T_c) exhibits a strong downward multiplicative renormalization in the underdoped regime. This strong renormalization was also observed in YBCO [10, 11], in which context it was attributed to inhomogeneities induced by oxygen doping [11]. We must, however, rule out this explanation for our x = 0.105 LSCO sample in view of the sharpness of the SC transition (∆T_c = 1.5 K). Instead, we believe that the proper interpretation of Fig. 4b is that of a universal doping dependence of ∆_sg/(k_B T_c)(Opt) with a linear regime that defines the approach to optimal doping and an underdoped regime whose defining property is a doping dependent ∆_sg/(k_B T_c).

It is remarkable that ∆_sg/(k_B T_c) decreases in the underdoped regime, since this is opposite to the doping dependence of most energy features (maximum SC gap

FIG. 4: (a) Normalized ∆_sg versus normalized T_c for LSCO (open symbols) and YBCO (filled circles [10] and filled squares [11]). The open circles are taken from previously published data, x = 0.14 [23], x = 0.16 [3] and x = 0.17 [4] while open squares are from this work (x = 0.105) and Ref. [22] (x = 0.14). (b) Intensity at QIC, at the energy transfer hω = 0.5∆_0, and at H = 0 T versus T calculated within a phenomenological Fermi-liquid (PFL) approach. The solid (dashed) line uses the inverse lifetime Γ = 0.2∆_0 (Γ = 0.8∆_0).
or pseudogap) which are found, from ARPES measurements, to increase with underdoping \[8, 9\]. In a phenomenological Fermi-liquid (PFL) picture, which is relatively successful at optimal doping, the SG is directly related to the SC gap. Although its maximum increases with underdoping, the slope of the SC $d$-wave gap has been measured to soften at the nodes with underdoping \[28\]. This means that the ratio $\Delta_{sg}/(k_B T_c)$ will decrease with underdoping \[29\]. In this picture, the anomaly at $T_c$ in the temperature dependence displayed in Fig. 1b is caused by the closing of the SG upon entering the normal state. In Fig. 1b we show the calculated dependence on temperature of the zero field neutron intensity at $Q_{IC}$ and energy transfer $\hbar \omega = 0.5 \Delta_0$ using the PFL parameters chosen to reproduce the $T$ dependence at optimal doping \[30\]. A cusp-like anomaly at $T_c$ separates the normal regime from a $d$-wave SC regime with a decreasing residual intensity due to a phenomenological inverse life-time of $\Gamma = 0.2 \Delta_0$. In this spirit, to reproduce the measured residual spectral weight at low $T$ in $x = 0.105$ LSCO would require $\Gamma \approx \Delta_{sg}$ resulting in strong broadening of the peak at $T_c$ as shown in Fig. 1b. Thus, the naive PFL approach is unable to reconcile a sharp anomaly at $T_c$ ($\Delta_{sg}$) for small enough $\hbar \omega$ (T) and the large, compared to optimal doping, residual intensity in the low-$T$ (low-$\hbar \omega$) tail of Fig. 1b (Fig. 3b).

One way to explain the large residual intensity at low temperatures and energies in strongly underdoped HTSC could be in terms of a two-component model. The first component would correspond to the gapped response seen around optimal doping. The second (quasi-elastic) component could be related to the slowing down of the magnetic signal observed by $\mu$SR \[31\], and the central mode recently reported in YBCO ($T_c = 18$ K) \[32\]. The fact that both components develop well-defined peaks at $Q_{IC}$ suggests an inter-twinning of the two components on a nanometer length scale. This could possibly be explained within a picture of static and fluctuating stripes, although it remains a challenge to quantify this picture to describe the detailed field and temperature effects of the magnetic response reported here.

In summary, we have reported a dramatic field-induced enhancement of the INS response for low energy transfers in a restricted temperature range. The field dependence suggests that the approach developed \[15\] to explain the previously observed field-induced static magnetic order \[16\] (see also Ref. 17) may also be applicable to the dynamics. The field-induced excitation may be more difficult to capture in a PFL approach. Furthermore, we have identified a SG, $\Delta_{sg} = 1.5$ meV in underdoped LSCO $x = 0.105$. The strong renormalization of the SG as a function of underdoping appears to be a generic feature of HTSC and might signal a profound modification of the underlying electronic excitations as the system approaches its Mott insulating phase. In particular, we are not dealing with a simple damping or smearing of the gap. The cusp upon heating through $T_c$ implies that the gap remains well-defined as it closes in energy, which also indicates that the SG is directly coupled to the SC-order parameter.
