Gravitational waves in models with multicritical-point principle

Yuta Hamada,* Hikaru Kawai,† Kiyoharu Kawana,‡ Kin-ya Oda,§ and Kei Yagyu¶

Abstract

The multicritical-point principle (MPP) provides a natural explanation of the large hierarchy between the Planck and electroweak scales. We consider a scenario in which MPP is applied to the Standard Model extended by two real singlet scalar fields $\phi$ and $S$, and a dimensional transmutation occurs by the vacuum expectation value of $\phi$. In this paper, we focus on the critical points that possess a $\mathbb{Z}_2$ symmetry $S \rightarrow -S$ and all the other fields are left invariant. Then $S$ becomes a natural dark matter (DM) candidate. Further, we concentrate on the critical points where $\phi$ does not possess further $\mathbb{Z}_2$ symmetry so that there is no cosmological domain-wall problem. Among such critical points, we focus on maximally critical one called CP-1234 that fix all the superrenormalizable parameters. We show that there remains a parameter region that satisfies the DM relic abundance, DM direct-detection bound and the current LHC constraints. In this region, we find a first-order phase transition in the early universe around the TeV-scale temperature. The resultant gravitational waves are predicted with a peak amplitude of $O(10^{-12})$ at a frequency of $10^{-2} - 10^{-1}$ Hz, which can be tested with future space-based instruments such as DECIGO and BBO.

1 Introduction

Gravitational Wave (GW) astronomy \cite{1, 2, 3} is one of the most fascinating research fields because it allows us to explore the physics of the early universe, complementary to the cosmic microwave background (CMB) observations. Gravitational waves from compact binaries \cite{4, 5, 6} and stochastic background \cite{7, 8, 9, 10, 11, 12} allow us to test new physics models as well as gravity theories. In particular, stochastic GWs originating from first-order phase transitions (FOPTs) \cite{13, 14, 15, 16} have received much attention in recent years, as many new physics models predict them in the early Universe, contrary to the pure Standard Model (SM), which shows a crossover electroweak (EW) transition \cite{17, 18}.

In this paper, we study the FOPT and the resultant GW signals in an extension of the SM by two real singlet scalars $\phi$ and $S$ that account for the hierarchy between the EW and Planck scales \cite{19, 20}. In the original Coleman-Weinberg (CW) mechanism \cite{21, 22}, the scalar field has a loop-suppressed mass compared to its vacuum expectation value (VEV), and cannot be regarded as the observed Higgs boson at LHC. That is why $\phi$ must be introduced in addition to the SM Higgs as a scale-generating scalar. On the other hand, the role of the gauge field in the original CW model can be played by $S$ \cite{23}. In this sense, this model \cite{19, 20} can serve as a minimal model of the scale generation. As a bonus, we can naturally identify $S$ as the weakly-interacting-massive-particle dark matter by imposing the $Z_2$ symmetry $S \rightarrow -S$, with all other fields being invariant.

The starting assumption of the CW mechanism is the absence of dimensionful parameters, especially the scalar mass-squared, in the tree-level Lagrangian. This assumption is sometimes called the classical conformality or the classical scale invariance \cite{24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39}, and can be naturally explained \cite{23, 22} as a consequence of the multicritical-point principle (MPP) \cite{40, 41}. There are several ways to describe the MPP, but a simple one is “the coupling constants of a theory should be tuned to one of the multicritical points at which some of the extrema of the low-energy effective potential are degenerate”; see Refs. \cite{42, 43, 44, 45, 46, 47, 19, 48, 20, 22, 49} for further discussion. In this sense, the MPP determines the couplings constants in the low-energy effective potential, and in particular, provides a natural answer to the fine-tuning problem.

Some of the mechanisms for realizing the MPP prefer criticalities with larger multiplicity \cite{42, 44, 22}. In this paper, for the first time, we consider the two-scalar extension of the SM with maximal multicriticality in the sense that all the superrenormalizable couplings of the effective potential are fixed to a multicritical point, that is, all the relevant parameters in the low energy effective theory are fixed by the MPP.

As a first attempt, we focus on a class of multicritical points at which the Higgs mass-squared vanishes along with its superrenormalizable couplings to $\phi$ or $S$. The problem is then reduced to finding a maximally multicritical point of the two-scalar subsystem. Indeed in Ref. \cite{22}, the maximally multicritical points of the two-scalar system with the $Z_2$ symmetry for $S$ have already been classified. Among them, the so-called 1234 case (CP-1234 in this paper) is of particular interest because it can realize the FOPT without domain-wall problems around the TeV scale.
The organization of the paper is as follows. In Section 2, we discuss the maximal criticality at CP-1234 for the two-scalar extension of the SM. In Section 3, we study the FOPT by computing the bounce action and by obtaining the critical, nucleation, and percolation temperatures from it. In Section 4, we study the GW signals from the FOPT. We find that the phase-transition strength parameters are typically \( \alpha = 10^{-2} - 10^{-1} \) and \( \beta/H = 10^2 - 10^3 \). These values imply that the FOPT is not much strong and the resultant GW signals are dominated by the sound wave contributions. The resultant peak amplitude can be as large as \( \mathcal{O}(10^{-12}) \) around the frequency \( 10^{-2} - 10^{-1} \) Hz, which can be tested by DECIGO and BBO. In Section 5, we provide a summary.

## 2 Model

We consider a model with two real singlet scalar fields \( \phi \) and \( S \) in addition to the SM particles. To make \( S \) a dark matter candidate, we impose an unbroken \( \mathbb{Z}_2 \) symmetry whose transformation property is defined as \( S \rightarrow -S \) and all the other fields to be even.\(^1\)

The tree-level Lagrangian is

\[
\mathcal{L} = \mathcal{L}_{\text{SM}} + \frac{1}{2} (\partial_\mu \phi)^2 + \frac{1}{2} (\partial_\mu S)^2 - V(H, \phi, S),
\]

where \( \mathcal{L}_{\text{SM}} \) is the SM Lagrangian without the Higgs potential for the SM doublet \( H \). The scalar potential is generally given by

\[
V(H, \phi, S) = \frac{\lambda_H}{2} (H^\dagger H)^2 + \frac{\lambda_{\phi S}}{4!} \phi^4 + \frac{\lambda_{\phi H}}{4!} \phi^2 S^2 + \frac{\lambda_{S}}{2} S^4 - \frac{\lambda_{\phi H}}{2} \phi^2 (H^\dagger H) + \frac{\lambda_{S H}}{2} S^2 (H^\dagger H) \\
+ \mu_1^2 (H^\dagger H) + \frac{\mu_S^2}{2} S^2 + \mu_{\phi H} \phi H^\dagger H + \frac{\mu_{\phi S}}{2} \phi S^2 + \mu_1^3 \phi + \frac{\mu_2^2}{2} \phi^2 + \frac{\mu_3^3}{3!} \phi^3.
\]

Here, the masses and couplings are the renormalized ones that appear in the low energy effective potential; we will discuss the concrete renormalization scheme in Eq. (4) and below.

We assume the \textit{maximal} multicriticality, in which all the superrenormalizable parameters, i.e., the \( \mu_i \) parameters given in the second line of Eq. (2), are fixed to one of the multicritical points in the parameter space by the MPP.

In particular, we focus on a class of multicritical points in which \( (\mu_H, \mu_S, \mu_{\phi H}, \mu_{\phi S}, \mu_1, \mu_2, \mu_3) \) are fixed to be \( (0, 0, 0, 0, \mu_1, \mu_2, \mu_3) \). The vanishing of the first four dimensionful parameters can be understood as follows. In the field space of \( (H, S, \phi) \), we focus on the region where \( H \) and \( S \)

\(^1\)This \( \mathbb{Z}_2 \) invariance can be viewed as a consequence of the MPP, as well as the maximal multicriticality that will be discussed below. In general, the existence of an accidental low-energy global symmetry can be viewed as a realization of multicriticality.
are small, and rewrite the potential (2) as
\[ V(H, \phi, S) = \frac{\lambda_H}{2} (H^\dagger H)^2 + \lambda_\phi \phi^4 + \lambda_S S^4 + \frac{\lambda_{SH}}{2} (H^\dagger H) \]
\[ - \frac{\lambda_{\phi H}}{2} [\phi - \tilde{\mu}^2_H] (H^\dagger H) + \frac{\lambda_{\phi S}}{4} [(\phi - \tilde{\mu}^2_s)^2 + \tilde{\mu}^2_s] S^2 \]
\[ + \mu_1^2 \phi + \frac{\mu_2^2}{2} \phi^2 + \frac{\mu_3^2}{3!} \phi^3. \]  
(3)

The point with \( \tilde{\mu}^2_H = \tilde{\mu}^2_S = 0 \) in the parameter space is multicritical in the following sense (see also Ref. [19]): if \( \tilde{\mu}^2_H < 0 \), then \( [(\phi - \tilde{\mu}^2_H)^2 + \tilde{\mu}^2_S] \) can change its sign when \( \phi \) is varied, and stability and instability of \( H \) around \( H = 0 \) is flipped; on the other hand, if \( \tilde{\mu}^2_H > 0 \), there is no such flip; in this sense \( \tilde{\mu}^2_H = 0 \) is a critical point; the same argument holds for \( \tilde{\mu}^2_S \). Hereafter, we choose such a multicritical point \( \tilde{\mu}^2_H = \tilde{\mu}^2_S = 0 \). Similarly, the point with \( \tilde{\mu}^2_H = \tilde{\mu}^2_S \) in the parameter space is critical in the sense that both the \( H \) and \( S \) directions near their origin become simultaneously flat at the point \( \phi = \tilde{\mu}^2_H (= \tilde{\mu}^2_S) \). Therefore, \( \tilde{\mu}^2_H = \tilde{\mu}^2_S = 0 \) and \( \tilde{\mu}^2_H = \tilde{\mu}^2_S \) is a triple-critical point. After choosing this point, we may redefine \( \phi - \tilde{\mu}^2_H \) as a new \( \phi \). This corresponds to the point with \((0, 0, 0, \mu_1, \mu_2, \mu_3) \) in the potential Eq. (2).

To obtain a maximal criticality, we need to fix the last three parameters \((\mu_1, \mu_2, \mu_3) \) to a maximal (triple-)critical point. Indeed, the classification of the two-scalar system of \( \phi \) and \( S \) is given in Ref. [22]. Among the seven triple-critical points, the critical point \( 1234 \) (CP-1234) is of particular interest because it can realize the FOPT in the early universe without the domain-wall problem. We thus focus on the CP-1234 in this paper.

We briefly review the CP-1234 and the generalized CW mechanism [23] [22]. The one-loop effective potential with \( S = 0 \) at zero temperature in the \( \overline{\text{MS}} \) scheme is given by
\[ V_{\text{eff}} = \frac{\lambda_H}{2} (H^\dagger H)^2 - \frac{\lambda_{\phi H}}{2} \phi^2 (H^\dagger H) + \mu_1^2 \phi^2 + \frac{\mu_2^2}{2} \phi^2 + \frac{\mu_3^2}{3!} \phi^3 + \frac{\lambda_{\phi S}}{4!} \phi^4 + m_0^4(\phi) \ln \left( \frac{m_0^2(\phi)}{\mu^2 e^{3/2}} \right) + \frac{m_0^2(\phi)}{\mu^2 e^{3/2}} + \Delta V_{\text{1-loop}}(h, \mu), \]  
(4)

where \( \Delta V_{\text{1-loop}}(h, \mu) \) is the one-loop potential for the physical Higgs \( h \) at the renormalization scale \( \mu \), and the effective masses are given by
\[ m_0^2(\phi) = \mu_2^2 + \mu_3^2 + \frac{\lambda_{\phi H}}{2} \phi^2, \quad m_0^2(\phi) = \frac{\lambda_{\phi S}}{2} \phi^2. \]  
(5)

In Eq. (4), we have neglected the \( H \)-loop contribution to the \( \phi \) potential because we focus on the parameter region \( \lambda_{\phi H} \ll \lambda_{\phi S} \). Also, the \( H \) dependence in Eq. (5) are neglected because we consider the region \( \lambda_{\phi H} H^\dagger H \ll \lambda_{\phi S} \phi^2 \) and \( \lambda_{SH} H^\dagger H \ll \lambda_{\phi S} \phi^2 \). We choose the renormalization scale \( \mu = \tilde{M} \) at which \( \lambda_{\phi} = 0 \) [22]:
\[ V_{\text{eff}} = \frac{\lambda_H}{2} (H^\dagger H)^2 - \frac{\lambda_{\phi H}}{2} \phi^2 (H^\dagger H) + \Delta V_{\text{1-loop}}(h, \tilde{M}) + \frac{m_0^4(\phi)}{64\pi^2} \ln \left( \frac{m_0^2(\phi)}{\tilde{M}^2 e^{3/2}} \right) + \phi, \]  
(6)
where

\[ V_\phi(\phi) = \mu_1^3 \phi + \frac{\mu_2^2}{2} \phi^2 + \frac{\mu_3}{3!} \phi^3 + \frac{c}{48} \phi^4 \ln \left( \frac{\phi^2}{M^2} \right), \]  

(7)

in which

\[ c = \frac{3\lambda_\phi^2}{16\pi^2}, \quad M^2 = \frac{2\tilde{M}^2 e^{3/2}}{\lambda_\phi S}. \]

(8)

By neglecting the \( m_4^4(\phi) \) term in Eq. (6), the CP-1234 is realized as

\[ dV_\phi \bigg|_{\phi=\phi_S} = d^2V_\phi \bigg|_{\phi=\phi_S} = d^3V_\phi \bigg|_{\phi=\phi_S} = d^4V_\phi \bigg|_{\phi=\phi_S} = 0 \]

(9)

at the field point \( \phi = \phi_S \). These conditions completely fix the parameters of \( V_\phi(\phi) \) as

\[ \mu_1^3 = -\frac{c}{18} M^3 e^{-\frac{25}{4}}, \quad \mu_2^2 = -\frac{c}{4} M^2 e^{-\frac{25}{6}}, \quad \mu_3 = -c M e^{-\frac{25}{12}}, \quad \phi_S = -M e^{-\frac{25}{12}}. \]

(10)

Note that \( \mu_1^3, \mu_2^2, \) and \( \mu_3 \) are proportional to the one-loop suppression factor \( c \). This is consistent with having neglected the \( m_4^4(\phi) \) term because \( m_2^2(\phi) \) is proportional to \( c \) as we have chosen the renormalization point such that \( \lambda_\phi = 0 \). Substituting Eq. (10) into Eq. (7), we obtain

\[ V_\phi(\phi) = cM^4 \left[ -\frac{\phi}{18e^{25/4}} - \frac{\phi^2}{8e^{25/6}} - \frac{\phi^3}{6e^{25/12}} + \frac{\phi^4}{48} \ln \phi^2 \right], \quad \phi := \frac{\phi}{M}. \]

(11)

The corresponding potential is shown in Fig. [1] The VEV \( v_\phi \) at the true vacuum and the mass of \( \phi \) are numerically found to be

\[ v_\phi = 1.1M, \quad m_\phi^2 = -\frac{\lambda_H}{2} v^2 + 0.28cM^2. \]

(12)

The EW symmetry breaking is triggered by the mixing coupling \( \lambda_{\phi H} \), and the Higgs VEV is

\[ v := \sqrt{2}\langle H \rangle = v_\phi \sqrt{\frac{\lambda_{\phi H}}{\lambda_H}}, \]

(13)

where \( v \simeq 246 \) GeV. In the EW vacuum, the physical scalar states \( \hat{h} \) and \( \hat{h}_\phi \), which are defined as \( \hat{h} = \sqrt{2} Re H^0 - v \) and \( \hat{h}_\phi = \phi - v_\phi \), are mixed with each other. The squared mass matrix in the basis of \( (\hat{h}, \hat{h}_\phi) \) is given by

\[ M^2 = v^2 \begin{pmatrix} \lambda_H & -\frac{v}{v_\phi} \lambda_H \\ -\frac{v}{v_\phi} \lambda_H & \frac{m_\phi^2}{v^2} \end{pmatrix}. \]

(14)
Figure 1: Shape of the potential $V_{\phi}(\phi)$ normalized by $cM^4$ at the CP-1234.

By introducing the mixing angle $\theta$, the mass eigenstates of the Higgs bosons $(h, h_{\phi})$ are defined as

$$
\begin{pmatrix}
\hat{h} \\
\hat{h}_{\phi}
\end{pmatrix}
= \begin{pmatrix}
\cos \theta & -\sin \theta \\
\sin \theta & \cos \theta
\end{pmatrix}
\begin{pmatrix}
h \\
h_{\phi}
\end{pmatrix},
$$

and their squared masses and $\theta$ are expressed as

$$
m_h^2 = M_{11}^2 \cos^2 \theta + M_{22}^2 \sin^2 \theta - M_{12}^2 \sin 2\theta ,
$$

$$
m_{h_{\phi}}^2 = M_{11}^2 \sin^2 \theta + M_{22}^2 \cos^2 \theta + M_{12}^2 \sin 2\theta ,
$$

$$
\tan 2\theta = \frac{2M_{12}^2}{M_{11}^2 - M_{22}^2}.
$$

On the other hand, $S$ does not mix with $\hat{h}$ and $\hat{h}_{\phi}$ due to the $\mathbb{Z}_2$ parity, and so its squared mass is simply determined to be

$$
m_S^2 = \frac{1}{2}(v^2 \lambda_{SH} + v_{\phi}^2 \lambda_{\phi S}) .
$$

From the above discussion, two of the six dimensionless parameters $\lambda_H$, $\lambda_{\phi}$, $\lambda_S$, $\lambda_{\phi S}$, $\lambda_{\phi H}$, and $\lambda_{SH}$ in the potential are fixed by $v$ and the Higgs mass $m_h \simeq 125$ GeV. For simplicity, we choose $\lambda_S$ to be zero at the EW scale, since it does not play a phenomenologically important role. Thus, we can choose the free parameters as

$$
\{m_S, \lambda_{SH}, \lambda_{\phi S}\} \text{ or } \{m_S, \lambda_{SH}, v_{\phi}\}.
$$
In the latter, the input parameter $\lambda_{\phi S}$ is exchanged by $v_\phi$ via Eq. (19). Among these couplings, $\lambda_{\phi S}$ is the most important one for the discussion of the FOPT because it determines the finite temperature potential of $\phi$.

As aforementioned, $S$ is the dark matter candidate in this model. Its thermal relic abundance and the constraint from direct searches at XENON1T [50] have been investigated in Ref. [19] for some of double-critical points in the $(\mu_1^3, \mu_2^2, \mu_3^2)$ space. On the other hand, we study the maximal (triple-)critical point in the current paper. The differences in the predictions of $m_{h\phi}$ and $\theta$ from the previous analysis solely originate from the numerical factor 0.28 in Eq. (12). The current maximally critical model tends to predict a slightly larger mass of $h_\phi$ compared with the previous one. This makes the bound from the direct search slightly weaker. On the other hand, the relic abundance is well fitted by the following formula [19]:

$$4\lambda_{SH}^2 + \lambda_{\phi S}^2 = \left(\frac{m_S}{m_{th}}\right)^2,$$  

$$m_{th} = 1590 \pm 40 \text{ GeV}. \quad (21)$$

Table 1: Range of parameters allowed by all the constraints.

We note that in the numerical evaluation of the relic abundance and the constraint from the direct search, we employ the MicrOMEGAs package [51], and impose the relic abundance to be $\Omega_{S} h^2 = 0.12$ [52].

In Fig. 2, we show the regions allowed (non-shaded area) by various constraints on the $\lambda_{SH} - m_S$ plane. Each point in the allowed region satisfies the relic abundance, i.e., $v_\phi$ and $\lambda_{S\phi}$ are determined such that they satisfy Eqs. (19) and (21). The solid and dashed curves respectively show the contours of fixed values of $v_\phi$ and $\lambda_{S\phi}$, where the number is written along each curve. We also show the other constraints on the model parameters in the figure: The green, orange, gray, and cyan shaded regions are excluded by the updated XENON1T result [50], the LHC data, dark matter relic abundance, and perturbativity bound, respectively [19]. For the LHC bound, we demand that the signal strength of the Higgs boson $\mu_h$ is given within the 2σ range, where the current measurement with the integrated luminosity of 139 fb$^{-1}$ shows $\mu_h = 1.06 \pm 0.06$ [53]. In our scenario, $\mu_h$ can differ from unity due to the mixing with the singlet-like Higgs boson $h_\phi$, so this constraint can be described as $\sin^2 \theta \leq 0.06$. We see that the successful benchmark scenario is given at the well constrained region, i.e., 1.7 TeV $\lesssim m_S \lesssim 2.5$ TeV, 0.2 $\lesssim \lambda_{SH} \lesssim 0.75$, and 0.4 $\lesssim \lambda_{S\phi} \lesssim 0.8$. In Table 1, we show the range of parameters allowed by all the constraints discussed above for each fixed value of $v_\phi$.

3 First Order Phase Transition

In this section, we estimate the bubble nucleation and percolation temperatures of the FOPT using the effective potential of $\phi$ at finite temperature. For the model described in Section 2, we will see that the potential barrier disappears below $T = 0.26 T_c$ due to the existence of the linear term in the zero-temperature effective potential (6), where $T_c$ is the critical temperature at which the free energies of two vacua become degenerate. This implies that the percolation temperature cannot fall below 0.26 $T_c$. In Section 3.1, we study the effective potential of $\phi$ at finite temperature. We then discuss the nucleation and percolation in Section 3.2.

\textsuperscript{2}For the region with the dark matter mass larger than 1 TeV, we extrapolate the upper limit on the spin-independent cross-section for dark matter and nucleon scatterings.
### 3.1 Finite temperature potential

Let us study the one-loop effective potential at finite temperature. In general, the one-loop thermal correction is

$$V_{\text{1-loop}}^\text{th}(\phi, T) = \frac{T^4}{2\pi^2} \sum_i \left[ g_{B_i} I_{B_i} \left( \frac{m_{B_i}(\phi)}{T} \right) - g_{F_i} I_{F_i} \left( \frac{m_{F_i}(\phi)}{T} \right) \right], \quad (22)$$

where $g_{B_i}$ and $m_{B_i}$ ($g_{F_i}$ and $m_{F_i}$) represent the degrees of freedom and mass for boson (fermion), respectively, and the functions $I_B$ and $I_F$ are given by

$$I_B(a) = \int_0^\infty dx x^2 \log \left( 1 \mp e^{-\sqrt{x^2+a^2}} \right). \quad (23)$$

In principle, all the scalar fields may contribute to the one-loop potential of $\phi$. However, the contributions from $H$ and $\phi$ are smaller than from $S$ because $m_H^2(\phi) \ll m_S^2(\phi)$ and $m_F^2(\phi) \ll m_S^2(\phi)$ as discussed below Eqs. (5) and (10). Thus, it suffices to take into account the $S$ contribution only:

$$V_{\text{eff}}(\phi, T) = V_\phi(\phi) + \frac{T^4}{2\pi^2} I_B \left( \frac{m_S(\phi)}{T} \right), \quad m_S^2(\phi) = \frac{\lambda_{\phi S}}{2} \phi^2. \quad (24)$$

At high temperatures, the perturbative calculations may break down, and it is necessary to sum up all the relevant diagrams [54, 55]. The so-called daisy resummation in the Parwani scheme [56] can be obtained by simply replacing $m_S(\phi)$ with the thermal corrected effective mass $m_S^{\text{daisy}}(\phi, T)$:

$$V_{\text{eff}}^{\text{daisy}}(\phi, T) = V_\phi(\phi) + \frac{T^4}{2\pi^2} I_B \left( \frac{m_S^{\text{daisy}}(\phi, T)}{T} \right), \quad (25)$$

where

$$\left( m_S^{\text{daisy}}(\phi, T) \right)^2 = m_S^2(\phi) + \frac{\lambda_{\phi S} T^2}{2} J \left( \frac{m_S^2(\phi)}{T^2} + \frac{\lambda_{\phi S}}{24} \right), \quad (26)$$

$$J(\alpha) := \frac{1}{\pi^2} \frac{\partial}{\partial \alpha} I_B(\alpha) = \frac{1}{12} - \frac{\alpha^{1/2}}{4\pi} + \cdots. \quad (27)$$

In the upper-left panel in Fig. 3, we show $V_{\text{eff}}(\phi, T)$ (curves) and $V_{\text{eff}}^{\text{daisy}}(\phi, T)$ (dots) for different values of $T$. Although there actually exist tiny differences between these potentials, the difference is less than 1% even when $T/T_c \sim 1$ ($T_c$ is $\sim 0.28 M$ from the figure). Therefore, we use $V_{\text{eff}}(\phi, T)$ in the following discussion.

---

3In fact, the background mass of $\phi$ is $m_\phi^2(\phi) = \mu_2^2 + \mu_3 \phi/3 \propto \lambda_{\phi S}^2/16\pi^2$, from which we can estimate the mass ratio at around $\phi = M$ as $m_\phi^2(M)/m_S^2(M) \sim \lambda_{\phi S}^2/16\pi^2 \lesssim 0.06$ for $\lambda_{\phi S} \lesssim 1$. Thus, the contribution from $\phi$ is at most 10% of that from $S$. 

---
To understand the parameter dependence of the FOPT, it is convenient to normalize the effective potential by $cM^4$:

$$\bar{V}_{\text{eff}}(\bar{\phi}, \tau) := \frac{V_{\text{eff}}(\phi, T)}{cM^4} = -\frac{\bar{\phi}}{18e^{25/4}} - \frac{\bar{\phi}^2}{8e^{25/6}} - \frac{\bar{\phi}^3}{6e^{25/12}} + \frac{1}{48} \log \bar{\phi}^2 + \frac{2\tau^4}{3} I_B \left( \frac{\bar{\phi}}{\tau} \right), \quad \tau := \frac{T}{m_s(M)}. \quad (28)$$

One can see that the parameter dependence of the effective potential appears only through $\tau$ except for the overall normalization so that the critical behavior is determined only by the $\tau$ parameter. In the upper right panel in Fig. 3 we plot $\bar{V}_{\text{eff}}$ where the different colors correspond to the different values of $\tau$. The critical value of $\tau$, i.e., $\tau_c$ at which the two vacua are degenerate is numerically found to be

$$\tau_c = 0.39, \quad (29)$$
by which the critical temperature $T_c$ is determined to be

$$T_c = 0.39 \, m_S(M), \quad (30)$$

and hence $\tau = 0.39 \, T/T_c$.

There is another important value of $\tau$, denoted by $\tau_b$, at which the potential barrier disappears due to the linear term of the potential $V_\phi$ at zero temperature. The value of $\tau_b$ is numerically found to be

$$\tau_b = 0.10, \quad (31)$$

which corresponds to

$$T_b = 0.10 \, m_S(M) \simeq 0.26 \, T_c. \quad (32)$$

For illustration, in the lower panel of Fig. 3, $dV_{\text{eff}}/d\phi$ is shown for $\tau = 0.1$ (orange) and $\tau = 0.11$ (green). When $\tau = 0.11$, the derivative of the potential is always negative, which means that there is no potential barrier in this case. When temperature is $T_n \lesssim T \lesssim T_c$, the universe is supercooled, where $T_n$ is the bubble nucleation temperature. In the present case however, there is not large room for the supercooling because $T_b = 0.26 \, T_c$.

### 3.2 Nucleation and Percolation

We estimate the bubble nucleation and percolation temperatures. The dynamics of phase transition is determined by the decay rate of the false vacuum into the true vacuum per unit time and volume:

$$\Gamma(T) \sim T^4 \exp\left(-\frac{S_3(T)}{T}\right), \quad (33)$$

where $S_3$ is the $O(3)$-symmetric bounce action. The bubble nucleation is realized when

$$\frac{\Gamma(T_n)}{(H(T_n))^4} \sim 1, \quad (34)$$

where $H(T)$ is the Hubble scale at temperature $T$. In the radiation-dominated era, $H(T)$ is given by (see e.g. Ref. [57])

$$H(T) = 1.66 \sqrt{g_*} \frac{T^2}{M_P}, \quad (35)$$

where $g_* \sim 100$ is the effective number of massless degrees of freedom and $M_P = 1.2 \times 10^{19}$ GeV is the Planck mass. To estimate the nucleation temperature $T_n$, we evaluate $S_3$ at temperature $T$ given by

$$S_3 = \frac{4\pi M}{\sqrt{c}} \int_0^\infty d\rho \rho^2 \left[ \frac{1}{2} \left( \frac{d\bar{\phi}_B}{d\rho} \right)^2 + V_{\text{eff}}(\bar{\phi}_B; \tau) \right], \quad (36)$$
\[ \rho \text{ is the normalized radial coordinate of the 3-dimensional Euclidean space } r \text{ defined by } \rho = \frac{c^{1/2}}{2} M r. \] In Eq. (36), \( \bar{\phi}_B \) is the bounce solution of \( \bar{\phi} \) satisfying the following equation of motion:

\[
\frac{d^2 \bar{\phi}_B}{d\rho^2} + \frac{2}{\rho} \frac{d \bar{\phi}_B}{d\rho} = \frac{\partial V_{\text{eff}}}{\partial \bar{\phi}} \bigg|_{\bar{\phi} = \bar{\phi}_F}, \quad \frac{d \bar{\phi}_B}{d\rho} \bigg|_{\rho = 0} = 0, \tag{37}
\]

where \( \bar{\phi}_F \) is the location of the false vacuum near the origin, which is numerically obtained for each \( \tau \).

After the bubble nucleation, there is a temperature at which true vacuum bubbles start to form an infinite connected cluster. Such a temperature is referred to as the percolation temperature \( T_p \), which is customary estimated by

\[
I(T) \sim 0.34, \tag{38}
\]

where \( I(T) \) is the exponent of the probability of finding a point still in the false vacuum: \( p(T) = e^{-I(T)} \). It is given by

\[
I(T) = \int_{t_c}^{t} dt' \Gamma(t') a(t')^3 \times \frac{4\pi}{3} R(t,t')^3, \quad R(t,t') = v_w \int_{t'}^{t} \frac{ds}{a(s)}, \tag{39}
\]

where \( a(t) \) and \( v_w \) are the scale factor at time \( t \) and the bubble wall velocity, respectively. The determination of \( v_w \) is one of the challenging issues in the field of FOPTs \[59\]. We choose \( v_w = 0.5 \) \[60, 61\] as a benchmark value in this paper. For numerical evaluations, we determine \( T_n \) and \( T_p \) by assuming that Eqs. (33), (34), and (38) exactly hold. When \( g_* = 100 \) and \( M_P/T_n = 10^{17} \), the condition for \( T_n \) can be expressed as \( S_3/T_n \simeq 145 \).

In the left panel in Fig. 4, we plot the numerical values of \( S_3(T)/T \) for \( \lambda_{\phi S} = 0.6 \) by using the FindBounce package \[62\]. Here, the gray region represents \( \tau < \tau_b (= 0.10) \leftrightarrow T/T_c < 0.25 \), where the potential barrier no longer exists.

In the right panel in Fig. 4, we plot \( T_c \) (blue), \( T_n \) (orange), and \( T_p \) (green points) as functions of \( \lambda_{\phi S} \) for \( v_{\phi} = 3 \text{ TeV} \) and \( v_w = 0.5 \). As in the left panel, the potential barrier disappears in the gray region. One can see that there is no significant difference between \( T_n \) and \( T_p \) in the present model, which means that the percolation occurs soon after the onset of nucleation. Note also that \( T_n \) and \( T_p \) become smaller than \( T_b \) for \( \lambda_{\phi S} \lesssim 0.4 \). We have checked that this is the case for \( 3 \text{ TeV} \lesssim v_{\phi} \lesssim 10 \text{ TeV} \). In particular for \( v_{\phi} = 10 \text{ TeV} \), a FOPT cannot be realized consistent with other phenomenological constraints because the allowed region of \( \lambda_{\phi S} \) is smaller than 0.4 (see Table 1).

4 Gravitational Wave Signals

In this section, we study the GW signals produced by the FOPT. In general, there are three kinds of sources of the stochastic GWs produced during a FOPT: bubble collisions, sound waves, and

\[4\text{As a consistency check, we have also calculated the bounce action by using the CosmoTransitions [63] and obtained the same results within a few percent accuracy.}\]
magnetohydrodynamic (MHD) turbulence in the plasma \[60, 61\]. Typically, the dominant source is the sound waves as long as the FOPT is not too strong, i.e., \( \alpha \lesssim 1\) and \( \beta/H \gtrsim 100\) in the following notation.

### 4.1 Strength parameters

There are two important parameters, \( \alpha \) and \( \beta \), to determine the GW energy spectrum \( \Omega_{\text{GW}}(f) \) produced by a FOPT. The parameter \( \alpha \) measures the strength of the FOPT, which is defined by the ratio between the latent heat energy and the radiation energy \( \rho_R \):

\[
\alpha(T) := \frac{1}{\rho_R(T)} \left[ \Delta V_{\text{eff}}(T) + T \frac{\partial \Delta V_{\text{eff}}(T)}{\partial T} \right],
\]

where

\[
\Delta V_{\text{eff}}(T) = V_{\text{eff}}(\phi_{\text{false}}, T) - V_{\text{eff}}(\phi_{\text{true}}, T).
\]

We note that the second term in Eq. (40), i.e., the contribution from the difference of entropy, is negligibly smaller than the first term. The other parameter \( \beta \) is defined by

\[
\beta(T) := -H(T) T \frac{\partial \ln \Gamma(T)}{\partial T},
\]

which determines the duration of the FOPT and the characteristic frequency of the GWs. In the following, we will consider two commonly assumed options \( T = T_p \) and \( T = T_n \) for the typical temperature to evaluate \( \alpha \) and \( \beta \) \[60, 64, 61\].
In Fig. 5 we show our numerical results in the $\alpha$-$\beta$ plane for $v_\phi = 3$ TeV (left), $v_\phi = 4$ TeV (middle), and $v_\phi = 5$ TeV (right), where $\lambda_{\phi S}$ is varied in each contours within the range $0.4 \leq \lambda_{\phi S} \leq 1$. The orange and blue colors correspond to the choices $T = T_p$ and $T = T_n$, respectively. The orders of magnitude of $\alpha$ and $\beta/H$ are $10^{-2}$–$10^{-1}$ and $10^2$–$10^3$, respectively, indicating that the FOPT is moderate in this model. In particular, the large $\beta/H$ corresponds to the short duration of the FOPT, and this is why $T_n$ and $T_p$ are close to each other as seen in the previous section.

To obtain the GW spectrum, we also need to calculate the energy efficiency factor $\kappa_v$ which is defined as the fraction of vacuum energy that is transferred to the bulk motion of plasma. In this paper, we use the analytical fitting result presented in Ref. [65]:

$$\kappa_v = \frac{c_{s}^{11/5}}{(c_{s}^{11/5} - v_{w}^{11/5})\kappa_{B} + v_{w} c_{s}^{6/5}} \kappa_{A}$$

(for $v_w \lesssim c_{s} = 1/\sqrt{3}$),

where $c_{s} \sim 0.58$ is the speed of sound and

$$\kappa_A = \frac{6.9 \alpha}{1.36 - 0.037 \sqrt{\alpha} + \alpha},$$

$$\kappa_B = \frac{\alpha^{2/5}}{0.017 + (0.997 + \alpha)^{2/5}}.$$

### 4.2 Gravitational Wave Signals

We now have all the necessary inputs to calculate the GW signals from the FOPT. In this paper, we rely on the numerical fitting functions presented in Ref. [60]. Here, let us once again clarify the relevant parameters in our model. As discussed above, the strength parameters $(\alpha, \beta)$ are functions of $\lambda_{\phi S}$ and $v_\phi$, and they are constrained by the XENON1T experiment and the theoretical
Figure 6: GW spectra for $v_\phi = 3$ TeV (upper left), 4 TeV (upper right), and 5 TeV (lower). For each $v_\phi$, the results of taking the minimum and maximum allowed values of $\lambda_{\phi S}$ are shown as dashed and solid blue lines, respectively. The colored regions show the sensitivity curves for various future detectors.

In Fig. 6, we show the GW energy spectra for $v_\phi = 3$ TeV (upper left), 4 TeV (upper right), and 5 TeV (lower). For each $v_\phi$, the results of taking the minimum and maximum allowed values of $\lambda_{\phi S}$ are shown as dashed and solid blue lines, respectively. Here, the other parameters are chosen as

$$v_w = 0.5, \quad \epsilon = 0.05,$$

where $\epsilon$ denotes the energy fraction of the turbulent bulk motion. The colored regions show the sensitivity curves of future detectors. One can see that the peak amplitudes can become as large as $O(10^{-12})$ with a peak frequency $10^{-2} - 10^{-1}$ Hz, which can be tested by DECIGO and BBO.
5 Summary

As a minimal model to explain the electroweak scale that is exponentially smaller than the Planck scale, we have proposed the two-scalar extension of the SM with maximal multicriticality in the sense that all the superrenormalizable parameters of the scalar potential are fixed by the MPP. As a first trial, we focused on the class of criticalities in which $S$ has the $\mathbb{Z}_2$ symmetry $S \rightarrow -S$, the masses squared of $H$ and $S$ vanish, and the cubic couplings $\phi H^3 H$ and $\phi S^2$ vanish too. Then we can employ the classification of the maximally multicritical points of the two-scalar sector of $\phi$ and $S$ in Ref. [22]. Among them, the so-called CP-1234 case is phenomenologically interesting, in which $S$ acts as dark matter, and a FOPT can occur around the electroweak scale in the early universe.

In this paper, we have studied the dark matter abundance and the constraints from its direct detection as well as from the LHC data and the theoretical perturbativity bound. As a result, we have found an allowed region with the masses of dark matter $m_S$ and the additional neutral scalar boson $m_{\phi} \phi$ to be $1.8 \text{ TeV} \lesssim m_S \lesssim 2.5 \text{ TeV}$ and $60 \text{ GeV} \lesssim m_S \lesssim 220 \text{ GeV}$, respectively. In addition, the coupling constants are constrained to be $0.2 \lesssim \lambda_{SH} \lesssim 0.8$ and $0.1 \lesssim \lambda_{\phi S} \lesssim 1.1$. Then, we have studied the FOPT and the resultant GW signals. One of the interesting features of the maximum criticality is the presence of the linear term in the $\phi$ potential, which ensures that the system does not have a long supercooling period. We have calculated the phase-transition strength parameters and found $\alpha = 10^{-2} - 10^{-1}$ and $\beta/H = 10^2 - 10^3$ within the allowed region of parameters summarized above. These moderate values of strength parameters imply that the GW signals are dominated by sound wave contributions. We have found that the peak amplitude can become as large as $\mathcal{O}(10^{-12})$ around the frequency $10^{-2} - 10^{-1} \text{ Hz}$, which can be tested by future detectors such as DECIGO and BBO.

It would be interesting to study more general multicritical points of the two-scalar extension of the SM. As a different extension of the SM, the roles of $\phi$ and $S$ for the electroweak-scale generation can be played by a singlet complex scalar and another doublet Higgs, respectively. If this model has the Peccei-Quinn (PQ) symmetry [66, 67, 68, 69, 70, 71, 72, 73, 74], it can be the DFSZ axion model. In general, PQ symmetry is difficult to impose because it is violated by anomalies at the ultraviolet cutoff scale. However, the MPP can have a possibility to realize such a pseudo-symmetry as one of its multicritical points. This will be left for future investigation.

It would also be worth investigating the Higgs inflation in this model, and the effect of right-handed neutrinos, which makes the perturbativity bound milder, along the line of Ref. [20].
