Abstract: Reference evapotranspiration (ET0) is an important part of the water cycle and energy cycle during crop growth. Understanding the influencing factors and spatiotemporal variations of ET0 can guide regional water-saving irrigation and regulate agricultural production. Data for daily meteorological observations of temperature, relative humidity, wind speed, and sunshine hours from 38 surface meteorological stations were used to analyze the spatiotemporal variations and trends in Shandong Province from 1980 to 2019. (1) The ET0 from 1980 to 2019 was 1070.5 mm, and there was a significant downward trend in the climate tendency rate of −7.92/10 a. The climate of Shandong Province became warmer and drier. The average annual temperature showed a significant upward trend, while the average annual relative humidity and average annual sunshine hours showed significant downward trends. (2) The annual ET0 ratio in spring, summer, autumn, and winter was 29%, 40%, 21%, and 10%, respectively. (3) A change in Shandong Province’s interannual ET0 occurred in 2002, with a decrease of 130.74 mm since then. (4) The ET0 was positively correlated with temperature, wind speed, and sunshine hours and negatively correlated with relative humidity. This study provides a scientific basis for the regulation and control of agricultural production in Shandong Province.

Keywords: reference crop evapotranspiration; temporal and spatial distribution; meteorological factors; Shandong Province; Pearson correlation

1. Introduction

Crop evapotranspiration refers to the process of leaf water transpiration and soil water evaporation during the whole growth period of crops from sowing to maturity [1]. Reference crop evapotranspiration (ET0), as an important index to characterize potential evapotranspiration and to evaluate the degree of drought, water consumption by vegetation, production potential, and water supply and demand balance [2,3], plays an important role in the water and energy cycles during crop growth [4]. ET0 is an important element to understand global climate change and improve the utilization of agricultural water resources [5].

The amount of ET0 is likely affected to meteorological factors and crop conditions, which are the main influences on ET0 change and their influence will increase with global climate change [6]. The
spatiotemporal distribution of ET₀ trends and its influencing factors have been a focus of research within and outside China. From the point of international research, the ET₀ in Spain showed a significant downward trend from 1961 to 2011, mainly because of a decrease in relative humidity and a sustained and significant increase in wind speed [7]. Valentin et al. [8] found that an increase in temperature and precipitation in southern Russia and most parts of the United States caused ET₀ to increase. Goyal et al. [9] analyzed the response of ET₀ to meteorological factors of Rajasthan in India. They concluded that a decrease in wind speed and an increase in air temperature resulted in a decrease of ET₀. In Chinese domestic research, Qi et al. [10] showed that the average annual ET₀ of Heilongjiang Province in the past 50 years had a decreasing trend, and the spatial trend gradually decreased from west to east, from south to north. Through an analysis of the spatiotemporal variation of ET₀ in Jiangsu Province, Wang et al. [11] found that the ET₀ mainly showed a decreasing trend, although the ET₀ of southern Jiangsu showed an increasing trend. The average annual ET₀ has decreased since the 1980s. The study of spatiotemporal variations in ET₀ in the hilly region of central Sichuan by Feng et al. [12] found that the spatial distribution of ET₀ showed a decreasing trend from northeast to southeast to central areas. The study of Liu et al. [13] showed that, at different time scales, ET₀ in Beijing was mainly affected by different meteorological factors: the most influential factors affecting the annual time scale ET₀ are relative humidity and net radiation, and the factors that have a great influence on the daily time scale ET₀ are wind speed and temperature. Li et al. [14] analyzed the spatiotemporal characteristics of ET₀ on the Loess Plateau of China and predicted its future variation trend. These studies show that ET₀ changes have regional characteristics because of different climatic conditions, resulting in different spatiotemporal patterns and characteristics [15]. Shandong Province is located on the east coast of China, with an unstable, warm, temperate monsoon climate. As a large agricultural province in China, grain crops covered 11 million hectares in 2018, with a total output of nearly 150 million tons. However, the effective irrigation coefficient was only 0.47, and the per capita water resources were less than 1/6 of the whole country [16]. Drought and waterlogging have adverse effects on agricultural production and social economic development, so relevant research on spatiotemporal patterns of ET₀ is needed [17].

In addition, there are a large number of methods analyzing meteorological data. The Mann–Kendall (M–K) test is a trend analysis method that has been widely used in hydrology and meteorology in recent years. Zhao et al. [18] used the M–K test to study the annual ET₀ of Ningxia and found that ET₀ showed a downward trend and change occurred around 1990. Zhang et al. [19] showed that the standardized precipitation evapotranspiration index (SPEI) on the Loess Plateau decreased in 1990s. The climate tendency rate is often used to reflect the climate change trend. A positive value shows an upward trend, while a negative value indicates a downward trend. Wang et al. [20] analyzed variations in the temporal trends of ET₀ and precipitation in Heilongjiang Province using the climate tendency rate. Zuo et al. [21] showed that the spatial distribution of annual ET₀ of the Wei River basin decreased from northeast to southwest, and the spatial variation in ET₀ was significant. Interpolation methods have significant advantages in analyzing the spatial distribution characteristics and future trends of climate. Radial basis function (RBF) [22], kriging [23], Bayesian kriging regression (BKR) [24], inverse distance weight (IDW), and other interpolation methods have been widely used. Among them, IDW is a spatial distribution method that fully considers the regional relationship between various factors. Because of its simple principle and accurate results, it has been widely used in data interpolation processing. Many scholars have used the inverse distance weight difference (IDW) method to analyze the spatial distribution of ET₀, e.g., Han et al. [25] using IDW to analyze the spatial distribution characteristics of the Tarim basin. Based on the inverse distance weight method, Jia et al. [26] evaluated the applicability of the algorithm for ET₀ in the Yangtze River Basin.

From the above analysis, it is clear that the response of meteorological factors to ET₀ varies greatly on different spatial and temporal scales. Based on it, this study selected daily meteorological data from 38 surface meteorological stations in Shandong Province covering nearly 40 years. The FAO-56 Penman–Monteith method was used to calculate ET₀ and the IDW method was utilized to analyze the spatial distribution of ET₀ and meteorological factors. This study analyzed the change in
the ET₀ trend using the M–K test and examined the Pearson correlation coefficient between meteorological factors and ET₀. Analyzing the spatiotemporal distribution characteristics of ET₀ change on different time scales will provide a theoretical basis for water resources regulation, irrigation system design, and crop water management in Shandong Province.

2. Materials and Methods

2.1. Overview of the Study Area

Shandong Province, one of the coastal provinces in East China, is located in the east coast of China, 34°22.9′–38°24.01′ N, 114°47.5′–122°42.3′ E. It is referred to as Lu, and the provincial capital is Jinan. It is bordered from north to south by Hebei, Henan, Anhui, and Jiangsu provinces. The climate is a warm, temperate monsoon climate, the precipitation and hottest temperatures are concentrated in the summer, the spring and autumn are short, and the winter and summer are long. The research area and site distribution are shown in Figure 1.

![Figure 1. Distribution map of meteorological stations in Shandong.](image)

2.2. Data Sources and Processing

The meteorological data of this paper were from the China Meteorological Data Network (http://data.cma.cn). Daily meteorological data (maximum temperature, minimum temperature, average temperature, average relative humidity, wind speed, and sunshine hours) from 38 meteorological stations in the research area were selected. The meteorological factors are expressed as T_max, T_min, T, RH, WS, and SSD, respectively. There were 5.55 × 10^5 data points. Where part of the meteorological station daily value data was missing or abnormal, linear interpolation of mean or median value methods were used to supplement the missing data, according to the situation. Geographic information includes the latitude, longitude, and altitude of each site and administrative boundaries of the study area. The range of specific meteorological data is shown in Table 1.

| Meteorological Factors | T (°C) | RH (%) | WS (m/s) | SSD (h) |
|------------------------|--------|--------|----------|---------|
| Data range             | −50−50 | 0−100  | 0−20     | 0−20    |
| Data accuracy          | 0.1    | 1      | 0.1      | 0.1     |
2.3. FAO-56 Penman–Monteith Equation

The Penman–Monteith formula recommended in the 1998 FAO-56 paper was adopted. Based on the principle of energy balance and aerodynamics, the equation has a complete theoretical basis and high calculation accuracy and is widely used across the globe [27]. The Penman–Monteith model is expressed as follows:

\[
ET_0 = \frac{0.408\Delta (R_n - G) + \frac{900}{T + 273} U_2 (e_s - e_a)}{\Delta + \gamma (1 + 0.34U_2)}
\]  

(1)

where \(ET_0\) represents the reference crop evapotranspiration, mm/d; \(R_n\) net radiation, MJ/(m²·d); \(G\) is the soil heat flux density, MJ/(m²·d); \(T\), °C; \(e_s\) is the saturated vapor pressure, kPa; actual water vapor pressure is \(e_a\), kPa; \(\Delta\) is the slope of the saturation vapor pressure function, kPa/°C; the psychometric constant is \(\gamma\), kPa/°C; and \(U_2\) represents the wind speed at 2 m height, m/s.

2.4. Climate Tendency Rate

The climate tendency rate reflects the changing trend of climate elements, which can be calculated using linear regression. The calculation formula of linear regression coefficient \((a)\) sample \((Y)\) and time is as follows:

\[
Y_i = at + b
\]  

(2)

where \(t\), \(b\), and \(10 \times a\) are time series, empirical coefficient, and climate tendency rate, respectively.

2.5. Mann–Kendall Trend Testing

The M–K method is a non-parametric statistical test. Compared with parameter tests, the advantage of the M–K trend test is that its sample does not need to follow certain distribution requirements nor is it affected by a few outliers, so it is more suitable for type variables and sequential variables. The trend analysis method has been used widely in hydrology and meteorology in recent years [18]. In this paper, we used a confidence level of \(\alpha = 0.05\) to test the data and find out the change points through the M–K test and to analyze the trend of meteorological factors and evapotranspiration before, after, and throughout the year.

2.6. Pearson Correlation

Pearson correlation coefficients are often used to detect whether independent and dependent variables are correlated. Their values range between –1 and 1. The formula is as follows:

\[
P_{x,y} = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \cdot \sum (y - \bar{y})^2}}
\]  

(3)

where \(\sum (x - \bar{x})(y - \bar{y})\), \(\sqrt{\sum (x - \bar{x})^2 \cdot \sum (y - \bar{y})^2}\), and \(P_{x,y}\) are the covariance between variable \(x\) and variable \(y\), standard deviation between variable \(x\) and variable \(y\), and the correlation coefficient, respectively. The standard deviation (STDVP), root mean square error (RMSE), and Pearson coefficient of the \(ET_0\) and meteorological factors were calculated, and a Taylor correlation diagram was drawn [28].
2.7. **Inverse Distance Weighted Interpolation**

The IDW method in ArcGIS10.2 (ESRI, Redlands, CA, USA) was used to study the spatial distribution of regional ET0. IDW is a common and simple spatial interpolation method. It is based on the principle of similarity, that is, the closer the two objects are, the more similar their properties are. The distance between the interpolation point and the sample point is a weighted average, and the weight is given to the sample point [23]. The spatial distribution of ET0 and meteorological factors in Shandong Province were analyzed using IDW.

3. Results

3.1. **Temporal Variation of Meteorological Factors**

The interannual variation of meteorological factors in Shandong Province was uneven, and the values showed noticeable oscillations (Figure 2). \( T, T_{\text{max}}, \) and \( T_{\text{min}} \) all had an upward trend during the period 1980–2019, with a range of 2.5–3.5 °C and a climatic tendency rate of 0.37, 0.26, and 0.51 °C, respectively. the average annual \( T \) was 13.2 °C. Overall, the annual average \( RH \) was 66.5%, the climate tendency was −0.44%/10 a, and there was no obvious change trend. The overall average WS at 2 m showed a downward trend below the average of 2.16 m/s at the beginning of the 21st century, with an average reduction of 0.179 m/s per 10 years. The maximum SSD was 7.3 h in 1981, the minimum was 5.9 h in 2003, and the average over the years was 6.6 h, with an average reduction of 0.263 h per 10 years.
Figure 2. Temporal distribution trends of meteorological factors (a) daily mean temperature (T), (b) maximum temperature (Tmax), (c) minimum temperature (Tmin), (d) average relative humidity (RH); (e) wind speed at 2 m (WS); and (f) sunshine hours (SSD). Note * indicates a significant level of α = 0.05.

3.2. Spatial Distribution of Meteorological Factors

It can be seen from Figure 3 that the distribution of meteorological factors in Shandong Province was spatially variable. The RH distribution had latitudinal zonal characteristics, and the T, WS, and SSD differed with longitude. The average T range was 6.0–14.9 °C, which is relatively large. The highest-value areas were in southwest Shandong and parts of northern Shandong, with an average of 14.3 °C. Jiaodong, which is close to the Bohai Sea, and the Taishan area, which is at high altitude, had a low average T of only 10.7 °C. The RH ranged from 56.8% to 74.2%, showing a relatively large difference. The high-value areas were mainly distributed in Chengshantou on the Jiaodong Peninsula and Cao County in southwest Shandong, at 74.2% and 71.3%, respectively. The low-value centers were distributed in Jinan and Zibo in northern Shandong, at 56.8% and 61.3%, respectively. The average WS ranged between 1.25 and 5.09 m/s. Taishan Station had a high WS because of its high altitude, while the other high-value centers appeared on the Jiaodong Peninsula along the coast, especially Chengshantou, Long Island, and Weihai, with WS of 4.4, 4.8, and 3.5 m/s; respectively. The total range of SSD was 5.9–7.3 h. The highest-value locations were 7.25, 7.24, and 7.12 h in Longkou, Kenli, and Laizhou, while Liaocheng, Tancheng, and Xinxian had a lower annual SSD, with an average of 5.94 h.
Figure 3. Spatial distribution of meteorological factors (a) daily mean temperature ($T$), (b) average relative humidity ($RH$); (d) wind speed at 2 m ($WS$); and (d) sunshine hours ($SSD$).

3.3. Temporal Variation of $ET_0$

The average annual $ET_0$ of Shandong Province from 1980 to 2019 showed a downward trend, at a rate of $-7.92$ mm/10 a. The maximum interannual $ET_0$ was in 1981, at 1161.85 mm; the lowest was in 1985, at 992.77 (Figure 4a). There was a fluctuating downward trend up to 2010, with a slow upward trend after that. With respect to inter-decadal change, as shown in Figure 4b, the $ET_0$ declined from the 1980s to the 2010s, with a decline of 9.38, 5.88, and 13.11 mm per decade. The 1980s and 1990s showed a positive anomaly, which was largest in the 1980s. The 2000s and the 2010s showed a negative anomaly, which was largest in the 2010s. The accumulated anomaly of annual $ET_0$ was variable but generally upward, as shown in Figure 4c, peaking in 2002 and then gradually decreasing until 2016.

Figure 4. Anomaly and accumulated anomaly of annual evapotranspiration ($ET_0$), (a) 5a moving average of annual $ET_0$; (b) anomaly and decadal anomaly of annual $ET_0$; (c) accumulated anomaly of annual $ET_0$. 
The seasonal difference was also analyzed. Table 2 show that the spring ET0 had a slow upward trend, while the other three seasons showed a downward trend. The highest average annual ET0 in summer was 406.51 mm; the lowest in winter was 107.40 mm. The average spring and autumn ET0 were 334.32 and 222.24 mm, respectively. Overall, summer and spring ET0 was greater than autumn and winter ET0.

| Time    | Maximum Value/mm | Minimum Value/mm | Average Annual/mm | Climate Tendency Rate mm/10 a |
|---------|------------------|------------------|-------------------|-------------------------------|
| Spring  | 377.95           | 291.16           | 334.32            | 2.26                          |
| Summer  | 470.46           | 364.01           | 406.51            | −3.16 *                       |
| Autumn  | 250.01           | 195.93           | 222.24            | −5.33 *                       |
| Winter  | 125.02           | 83.32            | 107.40            | −1.57                         |
| Annual  | 1161.85          | 992.77           | 1070.55           | −7.92 *                       |

Note *indicates a significant level of α = 0.05.

### 3.4. Spatial Distribution of ET0

The ET0 of 33 sites (86%) in Shandong Province showed a downward trend (Figure 5a). Zibo, Laizhou, and Qingdao’s ET0 showed a large negative climate tendency rate of −39.18, −34.49, and −25.87 mm/10 a, respectively. Five sites showed an upward trend (14%), among which the ET0 of Heze, Wendeng, and Jiaozhou showed a large upward trend, of 30.07, 23.09, and 19.43 mm/10 a, respectively. Overall, the spatial distribution of ET0 from 1980 to 2019 was not uniform. As shown in Figure 5b, the high-value interannual ET0 areas were mainly distributed in northern Shandong, central Shandong, and the Jiaodong areas. The values in the south were relatively small. The spatial distribution characteristics of ET0 at each local site varied because of their geographical location and climate environment. The high-value areas were mainly distributed in Jinan, Zhangqiu, and Weihai, with ET0 values of 1257.35, 1185.34, and 1157.99 mm. Jinan and Zhangqiu are located on Mount Tai, with longer SSD and lower rainfall, so the ET0 was higher, while Weihai is located on the shore of Huang Hai, which is affected by ocean circulation and had high WS and humidity, so the ET0 was higher. The areas with low ET0 values were mainly distributed in Chengshantou and Taishan, with values of 949.42 and 958.45 mm. Chengshantou is located on the eastern end of Jiaodong Peninsula, facing the sea, and the low T lead to low ET0, while Taishan had low ET0 because of the terrain and abundant rainfall on the Taishan mountain.

The spatial distribution of seasonal ET0 was the highest in summer, with a variation range of 307.0–461.8 mm. With the exception of three sites (8%), which showed an upward trend, the remaining 35 sites (92%) had a downward trend. The highest value of summer ET0 appeared in Jinan and Zhangqiu, at 461.9 and 448.4 mm respectively. The lowest value appeared in Chengshantou, with an average of 306.7 mm. The ET0 changes in spring and autumn were 247.9–414.5 mm and 195.5–271.1 mm, respectively. About half the stations had a decreasing trend in spring, among which Zhangqiu and Heze had a large climate tendency rate of 13.8 and 13.1 mm/10 a, while Laizhou and Hanting had a small climate tendency rate of −9.0 and −9.8 mm/10 a, respectively. The spatial distribution of high and low ET0 values in spring and summer was approximately the same. The number of stations with a rising trend in autumn ET0 was one higher than that in summer. Wendeng and Jiaozhou had higher climate tendency rates of 8.1 and 5.9 mm/10 a, while Zibo and Hanting had smaller climate tendency rates of −12.7 and −13.2 mm/10 a, respectively. The highest autumn ET0 value appeared in Chengshantou, Long Island, and other places at 271.1 and 270.2 mm, respectively. The lowest value appeared in Feicheng, with an average of 195.4 mm. The winter ET0 was the lowest, with a range of 90.05–181.4 mm. Fifteen sites (39%) showed an upward trend, and the remaining 23 sites (61%) showed a downward trend. The highest value of winter ET0 appeared in Longkou (181.5 mm), while the lowest value appeared in Jiyang, with an average of 90.4 mm. On the whole, the ET0 of spring and summer decreased gradually from north to south, and the ET0 of autumn and winter increased gradually from west to east.
(a) Annual climate tendency rate
(b) Annual ET$_{a}$ trend
(c) Spring climate tendency rate
(d) Spring ET$_{a}$ trend
(e) Summer climate tendency rate
(f) Summer ET$_{a}$ trend
Figure 5. Spatial distribution of annual and seasonal evapotranspiration (ET₀) (b) annual, (d) spring, (f) summer, (h) autumn, and (j) winter. Climate tendency rate of annual and seasonal evapotranspiration (ET₀) (a) annual, (c) spring, (e) summer, (g) autumn, and (i) winter.

Figure 6 shows that, overall, the average proportion of spring, summer, autumn, and winter ET₀ over a whole year was 29%, 40%, 21%, and 10%, respectively. The contribution of summer ET₀ was the highest, and the decrease in summer ET₀ was the main reason for the decrease of annual average ET₀. The largest seasonal ET₀ difference was at Jinan station, reaching 349.9 mm. The ET₀ difference between summer and winter was only 157.8 mm, and the seasonal ET₀ change was not obvious. The seasonal ET₀ in the hilly area in southwest Shandong was quite similar, but the seasonal ET₀ was very different in the Jiaodong area.

Figure 6. Spatial distribution of the contribution of seasonal evapotranspiration to annual ET₀.
3.5. Mann–Kendall Trend Test

To explore the reasons for the overall downward trend of annual $ET_0$ in Shandong Province, the M–K trend method was used to test the annual $ET_0$. The UF curve represents the time series, and the UB curve represents the inverse time series (Figure 7). If the value of the UF curve is greater than 0, the time series shows an upward trend. The UF and UB intersection point with the line showing significance at 0.05 indicates an effective change. Figure 7 shows that the UF and UB curve of the interannual $ET_0$ of the study area intersected in 2002, indicating that the $ET_0$ change occurred in that year. The calculated decrease was 130.74 mm.

![Figure 7. The result of Mann–Kendall (M–K) trend test.](image)

To study whether the declining trend in $ET_0$ was related to meteorological factors, a trend test for $ET_0$ before, after, and during the change in relation to each meteorological factor was carried out, (Table 3). Prior to the change (1980–2002), $ET_0$ and other meteorological factors did not pass the test of significance at $\alpha = 0.05$, except for $SSD$. The $T$ and $RH$ showed an upward trend, and the other meteorological factors showed a downward trend. With the exception of $T$, the $ET_0$ and other meteorological factors showed a downward trend after the change (2002–2019) and over the whole period (1980–2019) and, except for $SSD$, the remaining factors were all statistically significant. The regional $ET_0$ showed a downward trend in the three periods, and the post-change statistic was $-1.28$, which was four times the level before the change. This indicated that the overall downward trend of $ET_0$ was largest in the period of 2002–2019. $T$ showed an upward trend in all three periods, which was consistent with the $T$ trend line in Figure 2a. $RH$ was 0.27 > 0 between 1980 and 2002, indicating an upward trend, but between 2002 and 2019, the statistics were $-1.44 < 0$, indicating a downward trend. Overall, the average $RH$ showed a downward trend. $WS$ and $SSD$ also decreased in the three periods.

| Time                  | $ET_0$  | $T$     | $RH$    | $WS$    | $SSD$  |
|-----------------------|---------|---------|---------|---------|--------|
| Before change (1980–2002) | $-0.31$ | 0.66    | 0.27    | $-0.10$ | $-0.26^*$ |
| After change (2002–2019)    | $-1.28^*$ | 0.50*   | $-1.44^*$ | $-0.33^*$ | $-0.07$ |
| Whole period (1980–2019)    | $-1.35^*$ | 0.44*   | $-0.68^*$ | $-0.194^*$ | $-0.25^*$ |

Note * indicates a significant level test of 0.05. $T$, $RH$, $WS$, and $SSD$ represent daily mean temperature, average relative humidity, 2 m high wind speed, and sunshine hours, respectively.

4. Discussion

The fifth Intergovernmental Panel on Climate Change (IPCC) assessment report indicated that between 1880 and 2012, average global warming was $0.85 \pm 0.2$ °C. In response, research into regional
climate systems in the context of global warming has become a focus [29]. The atmospheric evapotranspiration capacity can be characterized by $ET_0$, which is a basic parameter for estimating crop water demand, and is an important index for evaluating the degree of regional drought, water consumption by vegetation, and water supply and demand balance [30]. As an important agricultural area in China, the spatiotemporal variation characteristics of $ET_0$ and meteorological factors in Shandong Province were analyzed in order to guide irrigation in the region, to enhance the adaptability of agricultural production to climate change, and to improve resilience to climate disasters.

With regard to the meteorological factors influencing $ET_0$ in Shandong, the average annual values of $T$, RH, WS, and SSD were 13.2 °C, 66.5%, 2.16 m/s, and 6.6 h respectively over the last 40 a. The overall trend of RH, WS, and SSD decreased with time, and $T$ rose, indicating that the climate of Shandong Province has become warmer and drier. According to the background of global climate warming, this conclusion is consistent with that of Ma [31] on irrigation water demand and its influencing factors in Shandong Province. Dong et al. [32] found that the annual average $ET_0$ of the North China Plain was 1071.37 mm, and the $ET_0$ decreased over the past 53 years (~12.8 mm/10 a). This study found that, in the Shandong Province over the past 40 years, $ET_0$ overall showed a significant downward trend. The annual average was 1070.55 mm, and the decline rate was ~7.92 mm/10 a. With the exception of spring $ET_0$, which showed an upward trend of 2.26 mm/10 a, the $ET_0$ of other seasons showed a downward trend, and the climatic tendency rates for summer, autumn, and winter were ~3.16, ~5.33, and ~1.57 mm/10 a, respectively. The decrease in summer $ET_0$ was the main factor influencing the decrease of annual average $ET_0$ because of the high summer $T$. The $ET_0$ ratio of the summer $ET_0$ to that of the whole year was 40%, and the relative change rate was 26.2%, which was consistent with the seasonal analysis of $ET_0$ in Shandong Province by Dong et al. [33]. The M-K test showed that the trend in $ET_0$ changed in 2002 and the calculated decrease was 130.7� mm. On the one hand, the meteorological factors before and after the change point showed that RH had a slow upward trend at a rate of 0.27 before the change. On the other hand, WS showed a downward trend before and after the change point, and the downward trend was significant after 2002. The statistical values for WS were ~0.10 and ~0.33, respectively. The combined effect of these two factors—RH and WS—contributed to the downward trend in $ET_0$.

When studying the spatial distribution of $ET_0$ and its influencing factors in Shandong in the past 40 a, it was found that the spatial distribution of RH had obvious zonal characteristics, while the difference among $T$, WS, and SSD was related more to longitude. There were clear differences in the spatial distribution of meteorological factors. As is vividly shown in Figure 8, $T$ has a downward trend in the X axis in both east and west directions, because $T$ in the Jiaodong Peninsula is generally smaller than that of southwest Shandong. This is because the Jiaodong Peninsula is affected by the ocean monsoon climate because it is near the Yellow Sea and the Bo Sea, which reduces the average $T$. The $T$ showed a similar U-shaped trend to the north and south of the Y axis, which is consistent with the lower $T$ of Taishan and other places in the central Shandong area. This was due to the high terrain of Mount Tai, which resulted in an average $T$ of only 14.3 °C. The RH along the meridian showed a U-shaped trend of high and low between the two sides. The Jiaodong area had a higher RH than the southwest Shandong mountain area because of its coastal location. RH showed a downward trend along latitudinal lines, with the largest RH in southern Shandong. As a whole, the WS showed an increasing trend from west to east. Except for the high WS caused by the terrain in Mount Tai, the other high-value centers appeared in the coastal Jiaodong Peninsula. The Jiaodong Peninsula had large WS because of the monsoon climate. The SSD showed a gradual increasing trend from southwest to northeast of Shandong, with a variation range of 5.9–7.3 h. The overall change was small, because the average sea surface of the Yellow Sea in the Qingdao area is above the National Vertical Datum. Except for the Taishan area, the overall elevation gap in Shandong was small, resulting in no clear change in SSD.
Figure 8. Spatial trends in meteorological factors. (a) daily mean temperature ($T$); (b) average relative humidity ($RH$); (c) wind speed at 2 m ($WS$); and (d) sunshine hours ($SSD$). Green curve is the fitting curve of the point projected from the meteorological data value to the Z,X plane, which represents the change trend in the longitude direction; similarly, the blue curve represents the change trend in the latitude direction.

On the whole, the distribution of spring and summer ET$_0$ in Shandong Province decreased from west to east and from south to north; the distribution pattern of autumn ET$_0$ was reversed for winter ET$_0$ (Figure 9). The spatial trend of interannual and seasonal ET$_0$ was clearly different. We analyzed the distribution of interannual and seasonal ET$_0$ further with the spatial trend map. The interannual ET$_0$ showed an approximate $n$-shaped pattern of low and middle values along the meridional direction, which followed the decreasing zonal trend from north to south. Therefore, the annual high-value area was mainly distributed in the middle and north of Lu, while the values in the south were relatively small. The spatial trend in ET$_0$ for spring and summer was similar to that of interannual ET$_0$, both of which decreased from west to east and from south to north. This was probably because the sum of ET$_0$ in spring and summer accounted for about 70% of the interannual ET$_0$ ratio. The change in ET$_0$ space in autumn and winter showed an obvious increasing trend from southwest to northeast. The autumn and winter periods were vulnerable to strong cold air, so $T$ decreased and WS increased, which led to a trend of spatial change similar to that of $T$ and WS, which was consistent with the quantification of causes for ET$_0$ in Shandong Province by Dong et al. [34].

Figure 9. Spatial trends in annual and seasonal evapotranspiration (ET$_0$) (a) spring; (b) summer; (c) autumn; (d) winter; and (e) annual.

To explore the relationship between ET$_0$ and its influencing factors further, a Taylor correlation chart was drawn using ET$_0$ as reference point (Figure 10). With the exception of RH, the Pearson correlation coefficient between the other meteorological factors and the ET$_0$ was positive, that is, an increase in the values of the meteorological factors will lead to an increase in ET$_0$. The correlation between $T$ and ET$_0$ was the most significant, reaching 0.93, and the correlation coefficients between
ET₀ and WS and SSD were 0.48 and 0.60, respectively. The RH was negatively correlated with ET₀, and the correlation coefficient was −0.49. This was consistent with the correlation analysis of ET₀ and meteorological factors in Shandong Province by Wang et al. [35] By comparing the Pearson correlation coefficients, it was found that T and SSD were the main meteorological factors affecting ET₀ change. As the global warming increases, the impact on the ET₀ of Shandong will gradually increase. At a next step, therefore, it is necessary to select the main grain crops, such as corn and wheat, and clarify the effect of climate change on the ET₀ of different growth periods in combination with the whole growth period. This will provide a theoretical basis for the construction of climate-adaptive cultivation models and irrigation methods for typical crops.

**Figure 10.** Taylor chart of correlation between evapotranspiration (ET₀) and meteorological factors. Daily mean temperature (T); average relative humidity (RH); wind speed at 2 m (WS); and sunshine hours (SSD).

5. Conclusions

(1) The average annual values for T, RH, WS, and SSD in Shandong Province from 1980 to 2019 were 13.2 °C, 66.5%, 2.16 m/s, and 6.6 h, respectively. The spatial distribution of RH had latitudinal zonal characteristics, and T, WS and SSD showed longitudinal variations.

(2) The average annual ET₀ of the last 40 years showed a downward trend, and the decline rate was −7.92 mm/10 a. From the 1980s to the 2010s, the decadal anomaly values decreased by 9.38, 5.88, and 13.11 mm per decade. Spring ET₀ showed a slow upward trend, the ET₀ of the other three seasons showed a downward trend. The spring, summer, autumn, and winter ET₀ as a proportion of that of the whole year was about 29%, 40%, 21%, and 10%. The highest contribution was from summer ET₀, and the decrease in summer ET₀ was the main reason for the decrease in annual ET₀. With regard to spatial distribution, spring and summer ET₀ generally showed a latitudinal distribution, decreasing from north to south, and autumn and winter ET₀ generally increased along a longitudinal gradient from west to east.

(3) The M–K trend test showed that interannual ET₀ change point in Shandong Province occurred in 2002, the reduction was about 130.74 mm. Annual ET₀ was positively correlated with T, WS, SSD, and negatively correlated with RH. T and SSD had the most significant correlation with ET₀, reaching 0.93 and 0.60, respectively. From the point of view of spatiotemporal distribution, this paper analyzed the trend and correlation of ET₀ with other meteorological factors in Shandong Province over the past 40 years. The findings can help to estimate and guide irrigation water demand, increase agricultural production, and resist meteorological disasters. In the case of global climate change anomalies, quantitative analysis is needed in order to find out the leading meteorological factors affecting ET₀ change in Shandong Province. This could provide a scientific basis for the regulation and control of agricultural production in Shandong Province.
Author Contributions: L.Z. collected the meteorological data; F.Z. and Z.L. analyzed the data; F.Z. and Z.L. wrote the paper; Z.L., L.Z., and J.Y. drew the figures for this paper; F.Z., Z.L., J.Y., K.S., and L.Y. reviewed and edited the paper. All authors have read and agreed to the published version of the manuscript.

Funding: This research was funded by the Major State Research Develop Program of China, grant numbers 2017YFD0301004 and 2016YFD0300201-3 and the Modern Agro-industry Technology Research System of Maize, grant number CARS-02-87.

Acknowledgments: We thank the Chinese meteorological data sharing service (http://data.cma.cn) for providing the meteorological data.

Conflicts of Interest: The authors declare no conflict of interest.
