**Objective:** Male genital tract infections have been associated with infertility, and *Escherichia coli* has drawn increasing attention as an important bacterium in this context. This investigation aimed to characterize and compare the distributions of O-antigen serogroups of *E. coli* in the semen samples of fertile and infertile men.

**Methods:** In this case-control study, semen samples were collected from 618 fertile and 1,535 infertile men. The *E. coli*-positive samples were evaluated in terms of concentration, morphology, viability, and motility parameters according to the World Health Organization 2010 guidelines. Finally, different serogroups of *E. coli* were identified by multiplex polymerase chain reaction targeting the O-antigen variations of the bacterium.

**Results:** The prevalence of *E. coli* among fertile men was significantly higher than among infertile men (\(p<0.001\)). The sperm morphology, viability, and motility in the *E. coli*-positive fertile group were significantly higher than in the *E. coli*-positive infertile group (\(p<0.001\)). *E. coli* O6 was the most prevalent serogroup found in both groups. However, there was no significant difference in the frequency of different serogroups of *E. coli* between the two groups (\(p=0.55\)).

**Conclusion:** Despite the higher prevalence of *E. coli* among fertile men, *E. coli* had more detrimental effects on semen parameters in infertile men. There was no significant difference in *E. coli* serogroups between the fertile and infertile groups.

**Keywords:** *Escherichia coli*; Male infertility; Semen; Serogroups

---

**Introduction**

Infertility is a worldwide health problem that causes an emotional impact in about 15% of cases. On average, male factor infertility is responsible for 50% of reproductive problems \([1]\). There is considerable variation in the causes of male infertility, including anatomical problems, hormonal disorders, genetic defects, infections, psychological conditions, and lifestyle factors. However, 25%–30% of couples have idiopathic infertility, meaning that the cause of infertility remains unknown \([2,3]\).

Urogenital tract infections (UTIs) are the main cause of infertility in male partners \([4]\). Studies have reported that UTIs are responsible for 8%–35% of male infertility cases \([5,6]\). Sexually transmitted diseases have negative effects on both spermatogenesis and sperm transfer from the testes to the ejaculation ducts \([7,8]\). In some cases, an infection may create an obstruction in the reproductive tract, thereby causing infertility \([9]\).

Several microorganisms have been isolated from the male repro-
ductile tract in infertile individuals. Microorganisms can cause infertility by various mechanisms, including sperm agglutination, immobilization of the spermatozoa by direct binding or production of immobile factors, interactions with the immune system and induction of chronic inflammation, alteration of the function of accessory sex glands, defects in sperm function, and a decreased proportion of spermatozoa with normal morphology [10,11].

Among bacterial species, *Escherichia coli* is the most common agent of male reproductive tract infections; therefore, it is the most prevalent microorganism isolated from urine and seminal fluid of patients with reproductive tract disorders. It is hypothesized that the presence of *E. coli*, as is the case for many other bacteria, may decrease sperm concentration, motility, and viability [12,13]. Although several studies have investigated the role of *E. coli* in male infertility, some reported there was no association between bacteria and male infertility [14,15]. According to a previous study, 174 O-serogroups have been identified for *E. coli*, that some of them are pathogenic [16]. The O1, O2, O4, O6, O16, O25, and O75 serogroups were predominantly found in uropathogenic *E. coli* [17].

No previous studies have compared different serogroups of *E. coli* in semen from fertile and infertile men. For this purpose, this study aimed to investigate the prevalence of *E. coli* and to identify *E. coli* serogroups in the semen of fertile and infertile men. In this study, serogroup identification was based on multiplex polymerase chain reaction (PCR), which is more accurate than serologic detection [16].

### Methods

#### 1. Study population

In this case-control study, 618 fertile and 1,535 infertile men with male factor infertility who were referred to the Yazd Infertility Research Center from April 2018 to October 2019 were voluntarily enrolled. All patients were diagnosed as fertile or infertile by a urologist according to the World Health Organization (WHO) 2010 guidelines [17], and then they were screened for the presence of *E. coli* in their semen. Participants who had used antibiotics within 2 weeks prior to the semen sampling, smokers, varicocelectomy, and samples with mixed infections were excluded. All participants provided written informed consent, the confidentiality of the identity and clinical information of the participants was guaranteed, and the ethical committee of the Research and Clinical Center for Infertility, Yazd, approved the study proposal (IR.IUMS.FMD.REC1396.9323133001).

#### 2. Sperm analysis

Semen samples were collected by masturbation into sterile tubes; the abstinence period for all participants was 2–5 days. Following liquefaction at 37°C for 20 minutes, the sperm morphology, concentration, viability, and motility parameters (including progressive motility, non-progressive motility and immotility), were evaluated according to the WHO guidelines for the examination and processing of human semen samples [18].

#### 3. Isolation of *E. coli* from semen

To isolate *E. coli*, the semen samples were streaked on plates containing eosin methylene blue using a sterile calibrated loop, and incubated at 37°C for 24–48 hours [19]. The *E. coli* colonies were phenotypically identified by Gram staining, followed by biochemical tests, including catalase, oxidase, lysine decarboxylase, sulfide-indole-motility, methyl red–Voges-Proskauer, triple sugar iron, and Simmons citrate.

#### 4. DNA extraction

A colony of the isolated *E. coli* was grown in 3 mL of tryptic soy broth at 37°C for 24 hours. Then, 1 mL of the bacterial suspension added into a sterile 1.5 mL micro-tube, centrifuged at 5,000 × *g* for 10 minutes, and washed three times by re-suspending the bacterial pellet in 1 mL of sterile phosphate-buffered saline and centrifuged at 6,000 × *g* for 4 minutes. The cells were lysed with 450 µL of lysis buffer (20 mM Tris, 25 mM EDTA, and 100 mM NaCl) and 50 µL of sodium dodecyl sulphate (10%) followed by incubation at 56°C for 20 minutes. Then, 300 µL of NaCl was added, mixed, and centrifuged at 12,000 × *g* for 10 minutes. The supernatant was equally transferred into two 1.5 mL micro-tubes, and 1 mL of cold absolute ethanol was added, mixed, and centrifuged at 12,000 × *g* for 15 minutes. Cold 70% ethanol (300 µL) was added, mixed, and centrifuged at 12,000 × *g* for 3 minutes. The supernatant was discarded, and the DNA precipitate was dissolved in 100 µL of sterile distilled water at 56°C for 10 minutes and kept at −20°C.

#### 5. Multiplex PCR

For the molecular characterization of 14 serogroups (categorized as group 1 and group 2) of the isolated *E. coli*, multiplex PCR was carried out using specific primers (Table 1), as previously described [16]. First, 1 µL of each pair of primers (0.5 µL of forward primer and 0.5 µL of reverse primer) of group 1 were mixed in a separate micro-tube; the same was done for the primers of group 2. The assay was then performed in a final volume of 20 µL consisting of 2 µL of template DNA, 10 µL of PCR master mix (Taq DNA polymerase 2X Master Mix Red, Ampliqon, Denmark), 7 µL of the primer pool (group 1 or group 2), and 1 µL of diethylpyrocarbonate-treated water (ddH2O). The thermal profile of the reaction for both groups was one cycle of primary denaturation at 94°C for 300 seconds, followed by 40 cycles of denaturation of DNA at 94°C for 60 seconds, primer annealing at 58°C for 60 seconds, extension at 72°C for 90 seconds, and final ex-
tension at 72°C for 300 seconds. The PCR products were detected by electrophoresis on 1% agarose gel containing DNA Green Viewer (P7890; ParsTous Biotechnology, Mashhad, Iran), using a 50 kbp DNA ladder (PR901633; Fermentas, Stanford, CA, USA) and under an ultraviolet Benchtop transilluminator (LTF00205; Bodensee, Baden-Württemberg, Germany). The amplified products were sequenced for final confirmation.

6. Statistical analysis

For the statistical analysis, the two-sample proportional test, Mann-Whitney U-test, and Student t-test were performed using IBM SPSS ver. 20 (IBM Corp., Armonk, NY, USA). The Student t-test (independent sample t-test) was used to compare sperm parameters between the fertile and infertile groups. The normality of the data distribution was checked using the Kolmogorov-Smirnov test. A p-value < 0.05 was considered to indicate statistical significance.

Results

The two groups were matched for demographic characteristics. The mean ages of the E. coli-positive fertile (ECPF) and E. coli-positive infertile (ECPI) groups were 31.0 ± 2.8 and 33.8 ± 6.2 years, respectively.

E. coli was isolated at a significantly higher frequency in the semen of fertile men than in that of infertile men (p < 0.001); 80 out of the 618 fertile patients (12.9%) had E. coli in their semen, comprising the ECPF group, while 80 out of the 1,535 infertile men (5.2%) had E. coli in their semen, comprising the ECPI group. The sperm parameters of the ECPF and ECPI groups are compared in Table 1.

Table 1. Primers used for multiplex PCR assays for 14 serogroups of the Escherichia coli isolated from the semen of fertile and infertile men

| Serogroup | Specific gene | Genbank accession No. or reference | Primer name | Primer sequence (5'-3') | Amplicon size (bp) | Concentration in multiplex PCR (µM) |
|-----------|--------------|-----------------------------------|-------------|-------------------------|-------------------|-----------------------------------|
| Group 1   |              |                                    |             |                         |                   |                                   |

The serogroups were divided into two groups according to a previous study [18].

PCR, polymerase chain reaction; F, forward; R, reverse.
The frequencies of normal morphology, motility, and viability of the sperm in the ECPF group were significantly higher than those in the ECPI group ($p < 0.001$). There was no significant difference in sperm concentration between the two groups.

Multiplex PCR was carried out in order to identify and compare the serogroup distributions of the bacterial isolates from the ECPF and ECPI groups. As shown in Table 3, the O2, O6, O7, O8, O15, O21, O25, O75, and O83 serogroups were detected in the ECPF group, and the O2, O6, O7, O8, O15, O25, and O75 serogroups were found in the ECPI group. O6 was the most prevalent serogroup found in both the ECPF (44.8%) and ECPI (50%) groups. The O8, O25, and O75 serogroups were the second most prevalent serogroups in the ECPF group, while O25 and O75 were the second most prevalent serogroups in the ECPI group (Table 3). However, there was no significant difference in the frequencies of different serogroups of $E. coli$ between the ECPF and ECPI groups ($p > 0.05$).

**Table 2.** Comparisons of the sperm parameters between the ECPF and ECPI groups

| Variable                  | ECPF ($n = 575$) | ECPI ($n = 1,725$) | $p$-value |
|---------------------------|-----------------|-------------------|-----------|
| Concentration ($\times 10^6$/mL) | 106.2 ± 53.2    | 98.8 ± 51.7       | 0.58      |
| Normal morphology (%)     | 7.3 ± 3.4       | 2.4 ± 2.5         | $< 0.001$ |
| Progressive motility (%)  | 61.3 ± 9.4      | 20.6 ± 5.3        | $< 0.001$ |
| Non-progressive motility (%) | 10.1 ± 5.7    | 9.2 ± 7.1         | $< 0.001$ |
| Immotile (%)              | 28.6 ± 7.6      | 70.2 ± 9.3        | $< 0.001$ |
| Viability                 | 42.6 ± 6.3      | 15.4 ± 3.5        | $< 0.001$ |

Values are presented as mean±standard deviation.

ECPF, *Escherichia coli*-positive fertile; ECPI, *E. coli*-positive infertile.

*A* $p$-value $\leq 0.05$ was considered to indicate a statistically significant difference between the ECPF and ECPI groups.

**Figure 1.** Results of multiplex polymerase chain reaction (PCR) divided into group 1 (A) and group 2 (B) for identification and comparison of serogroup distributions of *Escherichia coli* in the semen of the *E. coli*-positive fertile and *E. coli*-positive infertile groups.

**Discussion**

It has been accepted that reproductive bacterial infections are associated with male infertility [20]. Some studies have suggested that bacterial infections can induce inflammation or create changes in the biological or physiological function of the male reproductive system [21-23]. Filipiak et al. [24] found no statistically significant relationship between the presence of *E. coli* in semen and reduced sperm motility and morphology in infertile men. In contrast, Puerta Suarez et al. [25] reported that *E. coli* could significantly decrease sperm motility. However, the putative detrimental effect of *E. coli* on the seminal fluid and male infertility remains controversial [26,27]. In the present study, we evaluated the prevalence of *E. coli* isolated from semen samples of fertile and infertile men. To the best of our knowledge, this was the first study to compare the prevalence of different serogroups of *E. coli* in the semen of infertile and fertile men using multiplex PCR, which can detect serogroups of *E. coli* with high specificity and sensitivity. The principal limitation of this technique is...
that some samples were non-typeable, meaning that we could not detect the serotype with our primers. Furthermore, collecting this number of samples to analyze using multiplex PCR required a considerable investment of time and money.

Our results showed that the prevalence of E. coli in the semen of fertile men was significantly higher than in that of infertile men. Although the prevalence of E. coli was low in infertile men, the detrimental effect of E. coli on semen quality was more severe in this group. This finding is similar to previous clinical evidence showing that bacteria isolated from the genital tracts of normozoospermic men had no effect on semen quality; however, in infertile men, an impairment of sperm parameters was seen due to the diminished antioxidant capacity of sperm [28]. However, in line with our study, previous findings have confirmed that bacterial contamination of the semen samples of fertile men did not compromise the sperm quality, while in infertile men, it is possible that bacteria further deteriorated the overall quality of the seminal plasma [29]. Salisu et al. [30] reported that E. coli constituted one of the main microorganisms in the semen samples of infertile men, and also they concluded that high levels of E. coli had negative effects on sperm parameters, including sperm count, motility, and morphology.

Our results showed that sperm parameters such as motility, morphology, and viability were significantly impaired in infertile patients who tested positive for E. coli in comparison with the semen samples from healthy fertile men that tested positive for E. coli. Because both groups tested positive for E. coli, it can be inferred that E. coli may have a greater impact on infertile men due to etiology of male infertility. It has been suggested that E. coli can decrease male fertility potential by several mechanisms, including reduction of sperm parameters [31], defects in spermatogenesis, and reduction of the secretory capacity in the male accessory glands [32].

Infections of the accessory glands and male reproductive tract are harmful for sperm maturation. Epididymitis is a common urogenital disease in men between 18 and 50 years (the optimal age for fertility) [33]. Interestingly, E. coli has been found to be the most common cause of epididymitis and prostatitis [34]. Lang et al. [35] reported that alterations in spermatogenesis and defects in sperm structure occurred in almost 60% of patients with acute epididymitis.

The mechanism of the effect of E. coli on male fertility remains unknown, but it has been generally accepted that E. coli is the most common bacterium causing genital tract infections [36]. Fraczek et al. [37] reported that in vitro contact of E. coli with ejaculated spermatozoa can severely damage sperm membrane stability and mitochondrial activity. Defects in sperm membrane and activity were responsible for reducing male fertility potential. Another study evaluated the mechanism of the effects of E. coli on sperm and suggested that several soluble factors and adhesion molecules secreted by E. coli may be responsible for defects in sperm function, causing infertility in men [22].

It is noteworthy that microorganisms affect male infertility through various mechanisms, depending on the host immune system, age, sexual activity, and genetic background. Studies have reported that some microorganisms, including Streptococcus viridans, E. coli, Enterococcus faecalis, and Staphylococcus aureus together or alone, were harmful to male fertility potential [38,39]. In the present study, we only focused on E. coli as the most important bacterium in semen; other microorganisms were not evaluated.

Additionally, in the present study, molecular O-serogrouping of the E. coli isolates revealed slight differences in the serotype distribution between fertile and infertile men; however, these differences were not statistically significant between the two groups. E. coli O6 was the most common isolate in semen samples of both fertile and infertile men. This finding was similar to that of Lloyd et al. [40], who found the O6 serogroup in the semen samples. Furthermore, Boguen et al. [12] reported that the O1, O2, and O4 serogroups were the most prevalent serogroups of E. coli in the semen. Boguen et al. [41] reported that serogroups affected neither sperm viability nor mitochondrial membrane potential in infertile men. In that study, the O4 strain decreased sperm motility; however, we did not detect the O1 and O4 serogroups in the semen of either fertile or infertile men.

Based on the findings of this study, despite the higher prevalence

Table 3. Comparisons between the serogroups of the ECPF and ECPI groups

| Serogroups | ECPF | ECPI | p-value |
|------------|------|------|---------|
| O1         | 0    | 0    | -       |
| O2         | 2 (3)| 4 (6.25) | 0.37   |
| O4         | 0    | 0    | -       |
| O6         | 30 (44.8) | 32 (50) | 0.55   |
| O7         | 5 (7.5) | 4 (6.25) | 0.78   |
| O8         | 8 (11.9) | 4 (6.25) | 0.26   |
| O15        | 4 (6) | 4 (6.25) | 0.95   |
| O16        | 0    | 0    | -       |
| O18        | 0    | 0    | -       |
| O21        | 1 (1.5) | 0    | 0.33   |
| O22        | 0    | 0    | -       |
| O25        | 8 (11.9) | 8 (12.5) | 0.92   |
| O75        | 8 (11.9) | 8 (12.5) | 0.92   |
| O83        | 1 (1.5) | 0    | 0.33   |
| Total      | 67 (100) | 64 (100) | -      |

Values are presented as number (%). A p-value ≤0.05 was considered to indicate a statistically significant difference between the ECPF and ECPI groups; using this criterion, there was no significant difference in the serogroups of Escherichia coli between the two groups. The statistical analysis was conducted using the Mann-Whitney test. ECPF, Escherichia coli-positive fertile; ECPI, E. coli-positive infertile.
of *E. coli* in the semen of fertile men than in that of infertile men, the
distribution of *E. coli* subgroups did not show any significant differ-
ence between the two study groups. In this study, O6 was the most
common serogroup of *E. coli* in both groups. In addition, it seems
that *E. coli* may be responsible for changes in sperm parameters
including motility, morphology, and viability. More studies are sug-
uggested to clarify this issue in the future.
