On the migration of a system of protoplanets

W. Kley

1 INTRODUCTION

It is generally assumed that planetary systems form in a differentially rotating gaseous disc. In the late stages of their formation the protoplanets are still embedded in the protostellar disc and their orbital evolution is coupled to that of the disc. Gravitational interaction between the planets and the gaseous disc has basically two effects:

a) The torques by the planets acting on the disc tend to push away material from the orbital radius of the planet, and for sufficiently massive planets a gap is formed in the disc (Papaloizou & Lin 1984; Lin & Papaloizou 1993). The dynamical process of gap formation has been studied through time dependent hydrodynamical simulations for planets on circular orbits by Bryden et al. (1999) and Kley (1999, henceforth paper I). The results indicate that even after the formation of a gap, the planet may still accrete material from the disc and reach about 10 Jupiter masses ($M_{\text{Jup}}$). For very low disc viscosity and larger planetary masses the mass accumulation finally terminates (Bryden et al. 1999).

b) Additionally, the gravitational force exerted by the disc alters the orbital parameter (semi-major axis, eccentricity) of the the planet. Here, these forces typically induce some inward migration of the planet (Goldreich & Tremaine 1980) which is coupled to the viscous evolution of the disc (Lin & Papaloizou 1986). Hence, the present location of the observed planets (solar and extrasolar) may not be identical with the position at which they formed.

In particular, the migration scenario applies to some of the extra-solar planets (for a summary of their properties see Marcy, Cochran & Mayor 1999), the 51 Peg-type planets. They all have masses of the order $M_{\text{Jup}}$, and orbit their central stars very closely, having orbital periods of only a few days. As massive planets, according to standard theory, have formed at a few AU distance from their stars, these planets must have migrated to their present position. The inward migration was eventually halted by tidal interaction with the star or through interaction with the stellar magnetosphere (Lin, Bodenheimer & Richardson 1996). The only extrasolar planetary system known so far ($\upsilon$ And) consists of one planet at 0.059 AU on a nearly circular orbit and two planets at .83 and 2.5 AU having larger eccentricities (.18 and .41) (Butler et al. 1999).

In case of the solar system the question, what prevented any further inward migration of Jupiter, arises. As the net tidal torque on the planet is a delicate balance between the torque of the material located outside of the planet and the material inside (eg. Ward 1997), any perturbation in the
density distribution may change this balance. In this letter we consider the effect that an additional planet in the disc has on the migration rate. We present the results of numerical calculations of a thin, non-self-gravitating, viscous disc with two embedded protoplanets. Initially the planets with one $M_{\text{Jup}}$ each are on circular orbits at $a = 1a_{\text{Jup}}$ and $2a_{\text{Jup}}$, respectively. In contrast to the existing time-dependent models (Bryden et al. 1999; paper I) we take into account the back-reaction of the gravitational force of the disc on the orbital elements of the planets and star. The models are run for about 3000 orbital periods of the inner planet corresponding to 32,000 years. In Section 2 a description of the model is given, the results are presented in Section 3 and our conclusions are given in Section 4.

2 THE MODEL

We consider a non-self-gravitating, thin accretion disc model for the protoplanetary disc located in the $z = 0$ plane and rotating around the z-axis. Its evolution is described by the two dimensional $(r - \phi)$ Navier-Stokes equations, which are given in detail in Kley (1999, paper I). The motion of the disc takes place in the gravitational field of the central star with mass $M_\ast$, and the two embedded protoplanets with masses $m_1$ and $m_2$. In contrast to paper I we use here a non-rotating coordinate frame where the origin is located in the centre of mass of the two planets. We work here in an accelerated coordinate frame where the integration is over the whole disc surface, and $\Sigma$ denotes the surface density of the disc. The expressions for the gravitational potential is then given by

$$\Phi = -\frac{GM_\ast}{|r - r_\ast|} - \frac{Gm_1}{|(r - r_1)^2 + s_1|^1/2} - \frac{Gm_2}{|(r - r_2)^2 + s_2|^1/2}$$

(1)

where $G$ is the gravitational constant and $r_\ast$, $r_1$, and $r_2$ are the radius vectors to the star and two planets, respectively. The quantities $s_1$ and $s_2$ are smoothing lengths which are $1/5$ of the corresponding sizes of the Roche-lobes. This smoothening of the potential allows the motion of the planets through the computational grid.

The motion of the star and the planets is determined firstly by their mutual gravitational interaction and secondly by the gravitational forces exerted on them by the disc. The acceleration of the star $\mathbf{a}_\ast$ is given for example by

$$\mathbf{a}_\ast = -Gm_1 \frac{r_\ast - r_1}{|r_\ast - r_1|^3} - Gm_2 \frac{r_\ast - r_2}{|r_\ast - r_2|^3} - \nabla \Phi$$

(2)

where the integration is over the whole disc surface, and $\Sigma$ denotes the surface density of the disc. The expressions for the two planets follow similarly. We work here in an accelerated coordinate frame where the origin is located in the centre of the (moving) star. Thus, in addition to the gravitational potential, the disc and planets feel the additional acceleration $-\mathbf{a}_s$.

The mass accreted from the disc by the planets (see below) has some net angular momentum which in principle changes also the orbital parameter of the planets. However, this contribution is typically about an order of magnitude smaller than the tidal torque (Lin et al. 1999) and is neglected here.

As the details of the origin and magnitude of the viscosity in discs is still uncertain we assume a Reynolds-stress formulation (paper I) with a constant kinematic viscosity. The temperature distribution of the disc is fixed throughout the computation and is given by the assumption of a constant ratio of the vertical thickness $H$ and the radius $r$. Hence, the fixed temperature profile is given by $T(r) \propto r^{-1}$. We assume $H/r = 0.05$, which is equivalent to a fixed Mach number of 20.

For numerical convenience we introduce dimensionless units, in which the unit of length, $R_0$, is given by the initial distance of the first planet to the star $R_0 = r_1(t = 0) = 1a_{\text{Jup}}$. The unit of time is obtained from the (initial) orbital angular frequency $\Omega_1$ of the first planet i.e. the orbital period of the planet 1 is given by

$$P_1 = 2\pi t_0.$$  

(3)

The evolutionary time of the results of the calculations as given below will usually be stated in units of $P_1$. The unit of velocity is then given by $v_0 = R_0/t_0$. The unit of the kinematic viscosity coefficient is given by $\nu_0 = R_0v_0$. Here we take a typical dimensionless value of $10^{-3}$ corresponding to an effective $\alpha$ of $4 \times 10^{-3}$.

2.1 The numerical method in brief

The normalized equations of motion are solved using an Eulerian finite difference scheme, where the computational domain $[r_{\text{min}}, r_{\text{max}}] \times [\phi_{\text{min}}, \phi_{\text{max}}]$ is subdivided into $N_r \times N_\phi$ grid cells. For the typical runs we use $N_r = 128$, $N_\phi = 128$, where the azimuthal spacing is equidistant, and the radial points have a closer spacing near the inner radius. The numerical method is based on a spatially second order accurate upwind scheme (monotonic transport), which uses a formally first order time-stepping procedure. The methodology of the finite difference method for disc calculations is outlined in Kley (1989) and paper I.

The N-body module of the programme uses a forth order Runge-Kutta method for the integration of the equations of motion. It has been tested for long term integrations using the onset of instability in the 3-body problem consisting of two closely spaced planets orbiting a star as described by Gladman (1993). For the initial parameter used here, the error in the total energy after $1.2 \times 10^5$ orbits (integration over $10^8$ yrs) is less $2 \times 10^{-9}$.

2.2 Boundary and initial conditions

To cover the range of influence of the planet on the disc fully, we typically choose for the radial extent (in dimensionless units, where planet 1 is located initially at $r = 1$) $r_{\text{min}} = 0.25$, $r_{\text{max}} = 4.0$. The azimuthal range covers a complete ring $\phi_{\text{min}} = 0.0$, $\phi_{\text{max}} = 2\pi$ using periodic boundary conditions. To test the accuracy of the migration, a comparison calculation with $r_{\text{max}} = 8.0$ and higher resolution $N_r = 256$, $N_\phi = 256$ was also performed.

The outer radial boundary is closed to any mass flow $v(r_{\text{max}}) = 0$, while at the inner boundary mass outflow is allowed, emulating accretion onto the central star. At the inner and outer boundary the angular velocity is set to the value of the unperturbed Keplerian disc. Initially, the matter in the domain is distributed axially symmetric with a radial surface density profile $\Sigma \propto r^{-1/2}$.

© 0000 RAS, MNRAS 000, 000–000
Two planets, each with an initial mass of $1M_{\text{Jup}}$, are located at $r_1 = 1.0, \varphi_1 = \pi$ and $r_2 = 2.0, \varphi_2 = 0$. Thus, they are not only spaced in radius but are positioned (in $\varphi$) in opposition to each other to minimize the initial disturbance. The radial velocity $v$ is set to zero, and the angular velocity is set to the Keplerian value of the unperturbed disc.

Around the planets we then introduce an initial density reduction whose approximate extension is obtained from their masses and the magnitude of the viscosity. This initial lowering of the density is assumed to be axisymmetric; the radial profile $\Sigma(r)$ of the initial distribution is displayed in Fig. 1 (solid line). The total mass in the disc depends on the physical extent of the computational domain. Here we assume a total disc mass within $r_{\text{min}} = 0.25$ and $r_{\text{max}} = 4.00$ of 0.01 $M_\odot$. The starting model is then evolved in time and the accretion rates onto the planets is monitored, where a given fraction of the mass inside the Roche-lobe of the planet is assumed to accrete onto the planet at each time step and is taken out of the computation and added to masses of the planets. The Courant condition yields a time step of $6.810^{-4} P_1$.

3 RESULTS

Starting from the initial configuration (Fig. 1) the planets exert torques on the adjacent disc material which tend to push mass away from the location of the planets. At the same time the planets continuously accrete mass from its surroundings, and the mass contained initially between the two planets is quickly accreted by the planets and added to their mass. Finally one large gap remains in the region between $r = 1$ and $r = 2$ (Fig. 1).

Similarly to the one planet calculations as described in Bryden et al. (1999) and in paper I, each of the two planets creates a spiral wave pattern (trailing shocks) in the density of the disc. In case of one disturber on a circular orbit the pattern is stationary in the frame co-rotating with the planet. The presence of a second planets makes the spirals non-stationary as is seen in the snapshots after 50, 100, 250 and 500 orbits of the inner planet that are displayed in figure 2. Near the outer boundary at $r = 4$ the reflection of the spiral waves are visible. Using the higher resolution model with $r_{\text{max}} = 8.0$ (section /refbounds) we tested whether the numerical resolution or the wave reflection at $r_{\text{max}}$ has any influence on the calculation of the net torques acting on the planet and the accretion rates onto the planet. Due to limiting computational resources the higher resolution model was run only for a few hundred orbital periods and the largest difference (2.5%) occurred in the mass $m_3$ of the outer planet. The difference in radial position (migration) is less than 1%. We may conclude that our resolution was chosen sufficiently fine and that the reflections at the outer boundary $r_{\text{max}} = 4$ do not change our conclusions significantly.

In previous calculations (paper I) the equilibrium mass accretion rate from the outer part of the disc onto a one Jupiter mass planet for the same viscosity ($\nu = 10^{-5}$) and distance from the star was found to be $4.35 \times 10^{-3} M_{\text{Jup}}/yr$ for a fully developed gap. Here the accretion rate onto the planets is much higher in the beginning ($\approx 5 \times 10^{-4} M_{\text{Jup}}/yr$) as the initial gap was not as cleared. Thus, during this gap clearing process, the masses of the individual planets grows rapidly at the onset of calculations (Fig. 3). At $t \approx 250$ the mass within the the gap has been exhausted (see also Fig. 1) and the accretion rates $\dot{M}$ on the planets lower dramatically. At later times after several hundred orbits ($P_1$) they settle to nearly constant values of about $10^{-5} M_{\text{Jup}}/yr$ for the outer planet, and $2.2 \times 10^{-6} M_{\text{Jup}}/yr$ for the inner.
for the inner planet (from Fig. 3). Since the mass inside of planet 1 has left the computational domain and the initial mass between the two planets has been consumed by the two planets, this mass accretion rate onto planet 1 for later times represents the mass flow of material coming from radii larger than \( r_2 \) (beyond the outer planet). It is the material which has been flowing \( \text{across} \) the gap of the outer planet. Previously, this mass flow across a gap has been calculated (paper I) and the present results are entirely consistent with that estimate.

The gravitational torques exerted by the disc lead to an additional acceleration of the planets resulting in an expression similar to the acceleration of the star (Eq. [3]). For one individual planet this force typically results in an inward migration of the planet on timescales of the order of the viscous time of the disc (Lin & Papaloizou 1986). Here this inward migration is seen clearly for the outer planet in Fig. 4 where the time evolution of the semi-major axis of the two planets is plotted.

The inner planet on the other hand initially, for \( t < 200 \), moves slightly inwards but then the semi-major axis increases and, showing no clear sign of migration anymore, settles to a constant mean value of 1.02. However, the decrease of the semi-major axis of the outer planet reduces the orbital distance between the two planets. From three body simulations (a star with two planets) and analytical considerations (Gladman 1993; Chambers, Wetherill & Boss 1996) it is known that when the orbital distance of two planets lies below the critical value of \( \Delta_{\text{cr}} = 2\sqrt{3}R_H \), where

\[
R_H = \left( \frac{m_1 + m_2}{3m_*} \right)^{1/3} \frac{a_1 + a_2}{2}
\] (4)

is the mutual Hill radius of the planet, the orbits of the planets are not stable anymore. In the calculations this effect is seen in the strong increase of the eccentricity of the inner planet. At \( t = 2500 \) its eccentricity has grown to about \( e_1 = 0.1 \), while the eccentricity of the outer planet remains approximately constant at a level of \( e_2 = 0.03 \).

We should remark here that in the pure 3-body problem without any disc and the same initial conditions \( (r_1 = 1.0, m_1 = 1.0; r_2 = 2.0, m_2 = 1.0) \) for the three objects, the semi-major axis of the planets stay constant as this system is definitely Hill stable (Gladman 1993). However, if one takes as initial conditions for the pure 3-body system the parameters for the planets as obtained from the disc evolution at \( t = 2500 \) \( (r_1 = 1.0, m_1 = 2.3; r_2 = 1.5, m_2 = 3.2) \) then the evolution becomes chaotic on timescales of hundreds of orbits and the eccentricity grows up to \( e = 0.6 \) for both planets within 4000 orbits.

### 4 CONCLUSIONS
We have presented calculations of the long term evolution of two embedded planets in a protoplanetary disc that covers several thousand orbital periods. The planets were initially located at one and two \( a_{\text{Jup}} \) from the central star with initial masses of \( 1M_{\text{Jup}} \) each. The gravitational interaction with the gaseous disc having a total mass of \( 0.01M_\odot \) leads to an inward migration of the outer planet while the semi-major axis of the inner planet remains approximately constant and even slightly increased. At the same time, the ongoing accretion onto the planets increases their masses continuously until at the end of the simulation (at \( t = 2500 \)) the outer planet has reached a mass of about \( 3.2M_{\text{Jup}} \) and the inner planet of about \( 2.3M_{\text{Jup}} \).

This increase in mass and the decreasing distance between them renders the orbits eventually unstable resulting in a strong increase of the eccentricities on timescales of a few hundred orbits.

From the computations we may draw three major conclusions:

1) The inward migration of planets immersed in an accretion disc may be halted by the presence of additional protoplanets located for example at larger radii. They disturb the density distribution significantly which in turn reduces the net gravitational torque acting on the inner planet. Thus, the migration of the inner planet is halted, and its semi-major axis remains nearly constant.

2) When disc depletion occurs sufficiently rapid to prevent a large inward migration of the outer planet(s), a planetary system with massive planets at a distance of several \( \text{au} \) remains. This scenario may explain why for example in the solar system the outer planets (in particular Jupiter) have
not migrated any closer towards the sun.
3) If the initial mass contained in the disc is sufficiently large then the inward migration of the outer planet(s) will continue until some of them reach very close spatial separations. This will lead to unstable orbits resulting in a strong increase of the eccentricities. Orbits may cross and planets may then be driven either to highly eccentric orbits or may leave the system all together (see e.g. Weidenschilling & Marzari 1996). This may then explain the high eccentricities in some of the observed extrasolar planets in particular the planetary system of υ Andromedae.

As planetary systems containing more than two planets display different stability properties (Chambers et al. 1996) it will be interesting to study the evolution of multiple embryos in the protoplanetary nebula.

ACKNOWLEDGMENTS

I would like to thank Dr F. Meyer for lively discussion on this topic. Computational resources of the Max-Planck Institute for Astronomy in Heidelberg were available for this project and are gratefully acknowledged. This work was supported by the Max-Planck-Gesellschaft, Grant No. 02160-361-TG74.
