Abstract We present results from an analysis looking for dark matter annihilation in the Sun with the IceCube neutrino telescope. Gravitationally trapped dark matter in the Sun’s core can annihilate into Standard Model particles making the Sun a source of GeV neutrinos. IceCube is able to detect neutrinos with energies $>100$ GeV while its low-energy infill array DeepCore extends this to $>10$ GeV. This analysis uses data gathered in the austral winters between May 2011 and May 2014, corresponding to 532 days of livetime when the Sun, being below the horizon, is a source of up-going neutrino events, easiest to discriminate against the dominant
of the muon serves as a proxy for the direction of the initial neutrino and allows us to identify a directional excess from the Sun in reconstructed events.

We exploit this fact in the event selection (Sect. 4) for this analysis, using only seasons where the Sun is a source of up-going signal events. Furthermore we devise an event selection which minimizes atmospheric muon background contamination and limits the impact of mis-reconstructed events. The remaining samples of events are then analyzed using an unbinned maximum likelihood ratio method [7], looking for an excess of events from the direction of the Sun. This method compares the observed angles and energy spectrum to signal expectations from different simulated WIMP masses and annihilation channels (Sect. 5). Sections 6 and 7 present the results of this analysis as well as their interpretation in the framework of the larger effort to detect dark matter.

2 The detector

IceCube is a cubic-kilometer neutrino detector installed in the ice [8] at the geographic South Pole [9] between depths of 1450 and 2450 m. Neutrino reconstruction relies on the optical detection of Cherenkov radiation emitted by secondary particles produced in neutrino interactions in the ice or the nearby bedrock. The photons are detected by photomultiplier tubes (PMT) [10] housed in digital optical modules (DOM) [11]. Construction of the detector started in 2005 and the detector has been running in its complete configuration since May 2011, with a total of 86 strings deployed, each equipped with 60 DOMs.

The principal IceCube array consists of 78 strings ordered in a hexagonal grid with a string spacing of approximately 125 m, an inter-DOM spacing of 17 m along each string, and can detect events with energies as low as \( \sim 100 \text{ GeV} \). Eight infill strings are deployed in the central region of IceCube to form DeepCore, optimized in geometry and instrumentation for the detection of neutrinos at further lower energies, down to \( \sim 10 \text{ GeV} \). A layer of dust, causing a region of increased scattering and absorption, intersects the detector at depths between 1860 and 2100 m. Since the ice becomes more transparent at increasing depth, the main part of the DeepCore instrumentation is deployed below the dust layer with an inter-DOM spacing of only 7 m. A veto cap of additional 10 DOMs deployed above the dust-layer completes the DeepCore strings. A majority of the DeepCore DOMs are equipped with PMTs of higher quantum efficiency to increase light collection. These DeepCore strings, along with the seven adjacent standard IceCube strings, constitute the fiducial region of the DeepCore subarray for the purpose of this analysis [12]. For DM annihilations producing neutrinos above \( \sim 100 \text{ GeV} \), the full instrumented volume of the
neutralino annihilations in the Sun respectively, including absorption and neutrino oscillation effects (visible as wiggles in the plot on the left), as predicted by WimpSim [13]. The $\bar{\nu}_\mu$ fluxes are higher than the $\nu_\mu$ fluxes at lower energies since their interactions with the matter of the Sun are helicity suppressed.

3 Signal and background simulations

Neutrino flux predictions at Earth from WIMP annihilations in the Sun have been widely studied, for example in Ref. [13]. We use the flux predictions from DarkSUSY [14] and WimpSim [13] to simulate signals for the IceCube detector according to specific annihilation scenarios, incorporating effects from absorption in the Sun as well as neutrino oscillations [15]. Events from all three flavours of signal neutrinos are simulated. When WIMPs annihilate into $W^+W^-$ (see Fig. 1), the $W$ bosons decay promptly and neutrino emission from the leptonic decay channels peaks at energies close to the mass of the WIMP. The $\tau^+\tau^-$ channel produces a similar distribution of neutrinos in energy with a higher overall normalization. These are referred to as ‘hard’ channels. When the WIMP annihilates predominantly to a ‘soft’ channel such as $b\bar{b}$, the neutrino emission peaks at energies much below the mass of the WIMP, since the $b$ quarks hadronize before they can decay to produce neutrinos. WimpSim does not account for modifications to the spectrum originating from the radiation of electroweak gauge bosons by the intermediate and final states of the decay process. These effects have been studied in [16]. Since both $W^\pm$ and $Z$ bosons decay promptly to high energy neutrinos, the net effect of these electroweak corrections is to harden the fluxes from the softer channels and enhance signal rate expectations.

The principal background of muons generated in the interactions of cosmic rays with the Earth’s atmosphere is simulated using the CORSIKA package [17]. Atmospheric neutrino interactions with the ice and the bedrock surrounding the detector are simulated using neutrino-generator (NuGen) [18] above 150 GeV with the cross sections of [19] and GENIE [20] below 150 GeV. The atmospheric neutrino flux predictions of [22] are used to weight NuGen and GENIE simulated datasets to validate the data processing and event selection.

4 Event selection

The energy range of the expected signal (a few TeV at maximum) and the event topologies in the detector at these energies dictate the event selection strategies. For WIMP masses less than 200 GeV, which produce signal neutrinos mostly with energies below the IceCube threshold, only DeepCore will contribute significantly towards the effective volume. However, for higher WIMP masses, where a significant fraction of the resultant neutrinos are above the IceCube threshold, the full instrumented volume of IceCube comes into play. Consequently we select two non overlapping samples of events as illustrated in Fig. 2.

To optimize the event selections for the analysis, we consider two scenarios: WIMPs annihilating completely into $W^+W^-$ and WIMPs annihilating completely into $b\bar{b}$. For WIMP masses below 80.4 GeV, the mass of the $W$ boson, we consider the WIMP annihilating into $\tau^+\tau^-$, since annihilations to $W^+W^-$ are not kinematically allowed. Since the detector acceptance is energy dependent, cuts have to be optimized for the spectral composition of the expected signal flux.
Within IceCube, a standard set of filters pre-select signal-like events and reduce the rate of the dominant background of atmospheric muons, subsequent to which reconstructions specific to the event topology are carried out, at what is known as the filter level or level 2 (L2). We focus on a stream of data from three of these filters, a low-energy event filter on the topological region of DeepCore and two further filters selecting muon-like events in the bigger IceCube array. One of these filters favours short low energy upward going tracks. The other selects general bright track-like events, both up and down-going, where the latter class is restricted to events starting within the detector. After these filters the data rate is reduced from 3kHz to about 100Hz. Still, atmospheric muons constitute the overwhelming majority of events. At this stage, about 30% of the neutrino events recorded by IceCube include a coincident atmospheric muon event. The goal is to further reduce the data with a series of reconstructions and cuts to a sample of signal-like neutrino events. This sample will be, however comprised almost exclusively of atmospheric neutrino events, an irreducible background to the analysis. Figure 3 provides a comparative summary of the event rates at filter and analysis level.

4.1 Data treatment

The processing of IceCube data proceeds in sequential steps, referred to as selection levels. It involves the abstraction of the recorded analog to digital converter data as photons impacting on single PMTs (hits), the removal of nuisance hits caused by detector noise and coincident events, event reconstructions of increasing complexity and event selection cuts. The reconstructions assume single event topologies built up only by hits that are caused by the radiating particle. They can easily be misled by nuisance hits, making hit cleaning a priority for any IceCube analysis.

1 Two or more events being present in the detector at the same time and ending up in the same readout window. An effect observed in ~10% of recorded events, up to 30% depending on filter stream selection.

Fig. 2 The two event selection strategies for this analysis. The IceCube dominated high energy sample (a) is sensitive to neutrinos above ~100GeV. Most of the sensitivity for neutrino signals below 100GeV comes from the DeepCore (DC) dominated low energy sample (b). This approach is similar to that of earlier IceCube analyses [21].

This analysis makes use of a new approach for the necessary noise cleaning and separation of coincident events by an agglomerative hit clustering algorithm [23, 24]. It operates progressively on the IceCube data stream described by the time-distribution of hits. Within the algorithm, which takes into account the hexagonal design of the detector and the difference in instrumentation density between its components, the physical causal relation between consecutive hits is analyzed. If found to be causally connected, hits are considered to form a cluster. Clusters grow by further addition of more connected hits, while unconnected hits are rejected. Each such identified cluster can later be attributed to a particle (sub)event within the detector. Persistent errors, such as the splitting of a single event into two separate subevents are corrected by a subsequent algorithm described in [23], which probes the recombination of subevents back into a single event. The combination of these algorithms performs 50% better than previous approaches, in both selecting the correct hits created by the radiating particle as well as the correct separation of events arriving in coincidence.

4.2 IceCube event selection

From the ~100Hz of data from the three filters at L2, cuts favoring horizontal, well reconstructed events are used to...
select $\sim 3$ Hz of data (L3). The position of the Sun varies between $\sim 66^\circ$ and $104^\circ$ in zenith angle. Consequently the signal events are expected to be horizontal within the detector. Subsequently, events that have more hits outside the DeepCore fiducial volume or at least 7 hits in the IceCube strings are selected. More sophisticated and computationally intensive reconstructions are performed at this stage. A Bayesian likelihood-based reconstruction that uses the prior knowledge that the data are still dominated by down-going muons is used, along with consistency tests between the various track reconstructions performed so far. This reduces the data rate to $\sim 140$ mHz (L4). Subsequently, a Boosted [25] Decision Tree (BDT) is used to quantify each event as signal or background-like using a score, based on a set of variables describing the event topology and direction, as well as relative positions and arrival times of the various photon hits within the detector. The BDT is trained on simulated signal events of the $W^+W^-$-annihilation channel of 1 TeV WIMPs.

The optimum threshold on the BDT score was determined using the Model Projection Factor method described in [26] for the same signal hypothesis. The remaining $\sim 2.9$ mHz of data (L5) are dominated by up-going muons from charged current interactions of atmospheric $\nu_{\mu}$ (and $\bar{\nu}_{\mu}$). The angular resolution of this sample is further improved using a reconstruction which utilizes tabulated photon arrival time distributions obtained from simulation as described in [27]. The median neutrino angular resolution for this final sample ranges from $\sim 6^\circ$ for a 100 GeV neutrino to $< 1^\circ$ for a 1 TeV neutrino.

4.3 DeepCore event selection

The fiducial region of DeepCore is already embedded deep within the detector. In consequence, using a selection of DeepCore dominated events with less than 7 hits on regular IceCube strings (the compliment of the selection criterion for the IceCube event selection) already provides a certain degree of background rejection via containment and starting requirement for events. These two properties are further exploited for the identification of events originating from neutrino interactions.

The DeepCore event selection starts with events selected by any filter at L2. Straight cuts which enforce minimal event quality and a loose selection for low energy horizontal events are applied. To reject down-going events still contained in the sample, hit-based vetos requiring no hits in the outer and top-most DOMs are applied. Subsequently, events are reconstructed with the reconstruction described in [27] followed by further straight cuts, which reduce the content of atmospheric muons within the sample (L3+L4). After this a BDT, which is trained on the selection of track-like $\nu_{\mu}$-events by variables expressing the position, incoming direction and reconstruction quality of events, is used. Thereafter a cut is applied requiring the zenith angle to be reconstructed within $10^\circ$ of the actual Sun position. A second BDT, which is trained on the exact signal properties by additional energy-sensitive event variables, is used to further refine the event classification (L6). A loose cut on the second BDT-score sufficiently reduces the sample, so that the computationally demanding energy reconstruction described in [28] can be applied to all remaining events (L7). This reconstruction estimates the total energy of the incoming neutrino from the length of the muon track as well as the photons from hadronic debris from the charged current interaction, when the interaction has taken place within the instrumented detector volume. The sample now contains all variables needed for the likelihood analysis procedure. The BDT-score cut can be further optimized for the best sensitivity for a broad range of WIMP models at the low WIMP mass end and obtain the sample at L8.

The selection criteria described in the two sections above are applied to data from the austral winters between May 2011 and March 2014. This produces two non overlapping samples with the $\nu_{\mu} + \bar{\nu}_{\mu}$ effective areas and angular resolutions shown in Fig. 4, corresponding to 532 days of operation of IceCube-DeepCore. While this Tables 1 and 2 summarize the rates and neutrino purities of the two streams at various levels of the event selection.

During the austral summer, when the Sun is above the horizon and a source of down-going neutrinos, an additional background of down-going atmospheric muons, $\sim 10^5$ higher in rate than atmospheric neutrinos at filter level, dominates over the signal. For this data taking period, in order to reach a sample of suitable events for analysis, considerably harder cuts are required, diminishing the acceptance of neutrino events. Samples isolated from these periods of operation of IceCube-DeepCore [23, 29] have been found to not contribute significantly to the sensitivity and are thus not further considered.

5 Analysis method

An unbinned maximum likelihood ratio method [7] is subsequently used to look for a statistically significant excess of events from the direction of the Sun. The signal probability density function (p.d.f.), explicitly dependent on the event’s reconstructed direction, $\vec{x}_i$, energy, $E_i$, and observation time, $t_i$, is given by:

$$S_i(\vec{x}_i, t_i, E_i, m_\chi, c_\chi) = K(|\vec{x}_i - \vec{x}_0(t_i)|, \kappa_i) \times E_{m_\chi, c_\chi}(E_i),$$

(1)

where $K$ stands for the spatial and $E$ for the spectral parts of the p.d.f. and $m_\chi$ and $c_\chi$ stand for the mass and annihilation channel of the WIMP respectively. Here $K$ is approximated by the monovariate Fisher-Bingham distribution [30]...
Fig. 4 Event selection performance. Left $\nu_\mu + \bar{\nu}_\mu$ effective area, derived from Monte Carlo simulations performed using GENIE [20] for the DeepCore selection and NuGen [18] employing the cross sections as calculated by [19] for the IceCube selection. Right median angular resolution as a function of true neutrino energy. The dashed lines indicate the median kinematic angle between the incoming neutrino and the muon. Events from CC interactions of neutrinos with energies higher than $\sim 100$ GeV are preferentially included in the IceCube selection as the range of the muon is higher than the containment requirements of the DeepCore selection. Those that are included in the DeepCore selection are the ones of lower energy and those in which a larger fraction of the neutrino energy has been transferred to the hadronic cascade. For the latter events, a larger fraction of the observed photon yield comes from the hadronic cascade, affecting the performance of the track direction reconstruction. In addition the kinematic scattering angle also is higher for such events. Consequently, a saturation effect can be seen in both angular resolution and kinematic angle lines for the DeepCore Selection, at energies of $\sim 100$ GeV.

Table 1 Rate summary for the IceCube event selection. The signal efficiencies are with respect to L2 for the $1/2\mathrm{TeV} \rightarrow W^+W^-$ signal. The atmospheric muon neutrino rates indicate the sum of $\nu_\mu$ and $\bar{\nu}_\mu$ in the expected ratio. The discrepancy between the data rate at L2 and the total Monte Carlo rate is due to deficiencies in CORSIKA. As cuts reject most of the atmospheric muon background, the discrepancy becomes smaller. The final analysis method uses randomized data to estimate the background, and is not affected by this discrepancy.

| Cut level | Data (Hz) | CORSIKA (Hz) | Atmos $\nu_\mu$ (Hz) | Sig eff (%) |
|-----------|-----------|--------------|------------------|-------------|
| L2        | 98.4      | 72.8         | $18.6 \times 10^{-3}$ | 100         |
| L3        | 2.81      | 3.32         | $8.4 \times 10^{-3}$  | 82          |
| L4        | 0.14      | 0.15         | $5.2 \times 10^{-3}$  | 63          |
| L5        | $2.9 \times 10^{-3}$ | $0.8 \times 10^{-3}$ | $2.1 \times 10^{-3}$ | 37          |

Table 2 Rate summary for the DeepCore event selection. The signal efficiencies are with respect to L2 for the $50\mathrm{GeV} \rightarrow \tau^+\tau^-$ signal.

| Cut level | Data (Hz) | CORSIKA (Hz) | Atmos $\nu_\mu$ (Hz) | Sig eff (%) |
|-----------|-----------|--------------|------------------|-------------|
| L2        | 25.6      | 25.1         | $5.90 \times 10^{-3}$ | 100         |

Fig. 5 Distribution of the reconstructed energy (Reco) of the events for the DeepCore selection. For background and signal simulations, the true energy distribution (MC) is shown in dashed lines. The distributions for the signal are scaled down by a factor of 1/2 for improved visualization.

Fig. 6 Distribution of cosine of the opening angles towards the Sun observed in events of the IceCube (top) and DeepCore (bottom) samples. The black dots represent the number of events reconstructed at the corresponding direction, the red lines are the average background expectations with the gray shaded regions corresponding to statistical uncertainties on the background expectations, while the blue lines indicate the events expected from WIMPs of masses 1 TeV annihilating into $W^+W^-$ at $2.84 \times 10^{19} \text{s}^{-1}$ and 50 GeV annihilating to $\tau^+\tau^-$ at the rate of $3.46 \times 10^{22} \text{s}^{-1}$ respectively, the present upper limits. The analysis method employed is unbinned in direction, consequently the binning employed in this figure is for indicative purposes only.

The concentration factor $\kappa_i$ of the event $i$ is obtained from the likelihood-based estimate of the angular resolution of the track reconstruction [31]. The energy part of the signal p.d.f. is constructed from signal simulations.

The energy part of the signal and background p.d.f.s are the distributions of reconstructed energy obtained from signal simulations and observed data, respectively, and are used only for the DeepCore sample. They are illustrated in Fig. 5.

For a sample of $N$ events consisting of $n_s$ signal events from the Sun and $N - n_b$ background events, the likelihood can then be written as:

$$L(n_s) = \prod_{i} \left( \frac{n_s}{N} s_i + \left(1 - \frac{n_s}{N}\right) b_i \right)$$

The best estimate for the number of signal events in the sample is obtained by maximizing the likelihood ratio as defined in Ref. [7]. The significance of the observation can be estimated without depending on Monte Carlo simulations by repeating the process on datasets randomized in right ascension. As the two event selections have no events in common, they can be combined statistically using the method described in Ref. [32]. Confidence intervals on the number of signal events present within the sample are constructed using the method of [33].

5.1 Systematic uncertainties

Background levels are estimated in this analysis method using data randomized in right ascension (see Fig. 6) and so are, by construction, free of significant systematic uncertainties. A previous study of the signal uncertainties on data from the 79-string configuration of IceCube [21] concluded that the following sources of uncertainty are intrinsic to the signal simulation (percentage impact on sensitivity in parenthesis):

1. Neutrino-nucleon cross sections (7% at $m_\chi < 35 \text{GeV}$ down to 3.5% for $m_\chi > 100 \text{GeV}$)
2. Uncertainties in neutrino oscillation parameters (6%)
3. Uncertainties in muon propagation in ice (<1%),

while the following sources dominate the detection process

1. Absolute DOM efficiency
2. Photon propagation in ice (absorption and scattering).

Since the first class of sources of uncertainties, direct inputs to the WimpSim signal generator that mostly affect the signal flux normalisations, have not significantly changed with
respect to the study in Ref. [21], we assume them to be similar. The second class of sources of uncertainties also include effects altering the signal’s apparent spectral composition in the detection process and are thus more important to this analysis which is sensitive to the reconstructed event energy.

To study the effect of the absolute DOM efficiency as well as the absorption and scattering properties of the ice, a set of signal simulations were generated for one year of data by individually varying each quantities by $\pm 10\%$ from the baseline value for certain benchmark signals of interest.

The percentage impact of these variations on the muon flux $\Phi_{\mu+\bar{\mu}}$, which can be converted to the other quantities in Table 4, are summarized in Table 3. The percentage impact of the uncertainties on neutrino-nucleon cross sections, neutrino oscillations and muon propagation in ice are taken from [21] and summed in quadrature to the ones from uncertainties in DOM efficiency and ice optical properties to obtain the total systematic uncertainty.

6 Results

No significant excess of events over the expected background was found in the direction of the Sun, allowing us to set limits on the neutrino flux from the Sun in the GeV–TeV range. Assuming a conservative local DM density of 0.3 GeV/cm$^3$ [41], a standard Maxwellian halo velocity distribution and the Standard Solar Model, this limit can also be interpreted as a limit on the WIMP-proton scattering cross section. Table 4 summarizes the best fit number of signal events and the upper limit on the muon and neutrino fluxes, as well as spin-dependent and spin-independent WIMP-proton scattering cross sections.

7 Conclusions and interpretations

For spin-dependent WIMP-proton scattering, IceCube limits are the most competitive in the region above $\sim 80$ GeV (Fig. 7). The constraints on spin-independent scattering (Fig. 8) from this search are complementary to the limits from direct detection. Even though these tend to be significantly stronger, they are subject to different uncertainties from the nuclear scattering process and from astrophysics. Limits have improved by a factor of $\sim 2$ to 4 with respect to previous IceCube analyses [21,42]. While these constraints explicitly assume equilibrium between capture and annihilation in the Sun, for the natural scale of $(\sigma_A v) \sim 3 \times 10^{-26}$ cm$^3$s$^{-1}$ [43], the time required for equilibrium to be achieved becomes as large as the age of the Sun only for $\sigma_{\bar{p}-p}$ as low as $10^{-43}$ cm$^2$, making this a very reasonable assumption [44]. The uncertainties on these limits due to uncertainties in velocity distributions of DM have been quantified in Ref. [45] and do not exceed $\sim 50\%$. The study also concludes that these limits are conservative with respect to the possible existence of a dark-disk [46], since a population of DM particles with lower velocities in the disk will enhance the capture rate. For a dark disk contributing an additional 25% to the local DM density, co-rotating with the visible stellar disk with no lag in velocity and a velocity dispersion of $\sigma = 50$ km/s, the spin-dependent capture rate is boosted by a factor of $\sim 20$ at high DM masses, improving the constraint on the spin-dependent cross section by a corresponding amount.

As demonstrated in Fig. 7, these constraints exclude some models corresponding to neutralinos from a scan of $\sim 500$ million points in the 19 parameter realization of the phenomenological minimally super-symmetric standard model (pMSSM) [47,48] performed using micrOMEGAs [49] with logarithmicly distributed priors (chosen to preferentially populate low mass, high $\sigma_{\bar{p}-p}^{SD}$ models) on the mass parameters typically in the range 50–10,000 GeV/c$^2$. The points were required to yield a relic dark matter density consistent with PLANCK measurements [50] and a Higgs mass within the currently known uncertainty range [51], in addition to being consistent with recent measurements of the $B_0^0 \to \mu^+\mu^-$ branching ratio [52] and the CKM matrix element $V_{ub}$ [53]. Further details are given in [54].

Beyond the WIMP paradigm, this search is sensitive to any scenario with a DM particle in the 20 GeV to 10 TeV mass range that can scatter off nuclei sufficiently strongly to cause an over-density at the center of the Sun, and can annihilate to produce neutrinos as primary or secondary products. Some
### Table 4

$P$ values and 90% C.L. upper limits on the number of signal events within the two samples in $\sim$532 days of livetime, corresponding to three years of operation of IceCube-DeepCore in its final configuration. The average effective volumes over the three years are also provided, as well as upper limits on the muon flux, annihilation rate, and the spin-dependent and spin-independent WIMP-proton scattering cross sections.

specific scenarios have been considered in [55]. Scenarios where the DM-nucleon scattering is velocity or momentum dependent and hence suppressed at non-relativistic energies are also of particular interest [57]. In these scenarios, this search can be significantly more powerful than direct detection constraints, due to the fact that capture in the Sun for a DM-nucleus interaction that depends on the spin of the nucleus is dominated by scattering off light nuclei, while direct detection experiments on Earth rely on significantly heavier nuclear targets. Theories with DM candidates that interact very differently with protons and neutrons are also better constrained by this search, which relies on DM scattering off a democratic distribution of various nuclei present in the Sun, each with a different neutron-proton ratio. This is in contrast to direct detection experiments which often rely on a single target nucleus specimen [58,59].
