Understanding Higher-Order Shape via 3D Shape Attributes

David F. Fouhey, Abhinav Gupta, Andrew Zisserman

Abstract—In this paper we investigate 3D shape attributes as a means to understand the shape of an object in a single image. To this end, we make a number of contributions: (i) we introduce and define a set of 3D shape attributes, including planarity, symmetry and occupied space; (ii) we show that such properties can be successfully inferred from a single image using a Convolutional Neural Network (CNN); (iii) we introduce a 143K image dataset of sculptures with 2197 works over 242 artists for training and evaluating the CNN; (iv) we show that the 3D attributes trained on this dataset generalize to images of other (non-sculpture) object classes; (v) we show that the CNN also provides a shape embedding that can be used to match previously unseen sculptures largely independent of viewpoint; and furthermore (vi) we analyze how the CNN predicts these attributes.

Index Terms—3D Understanding, Shape Perception, Attributes, Convolutional Neural Networks

1 INTRODUCTION

Suppose you saw the sculpture in Fig. 1(a) on vacation and wanted to call your friend and tell her what you saw. How might you describe it so she would know that you were referring to the one in Fig. 1(a) and not the one in (b)? What you would not do is describe the sculpture pixel by pixel. Instead you would probably give a high level description in terms of overall shape, holes, curvature, sharpness/smoothness, etc. This is in stark contrast to most contemporary 3D understanding algorithms that in the first instance produce a metric map, i.e., a prediction of a local metric property like depth or surface normals at each pixel.

The objective of this paper is to infer such generic 3D shape properties directly from appearance. We term these properties 3D shape attributes and introduce a variety of specific examples, for instance planarity, thinness, point-contact, to concretely explore this concept. Although such attributes can be derived from an estimated depthmap in principle, in practice (as we will show with baselines) view dependence, insufficient resolution, errors and ambiguities in the reconstruction render this indirect approach inferior.

As with classical object attributes and relative attributes [16], [18], [53], 3D attributes offer a means of describing 3D object shape when confronted with something entirely new – the open world problem. This is in contrast to a long line of work which is able to say something about 3D shape, or indeed recover it, from single images given a specific object class, e.g. faces [8], semantic category [35] or cuboidal room structure [29]. While there has been success in determining how to apply these constraints, the problem of which constraints to apply is much less explored, especially in the case of completely new objects. Used appropriately, scene understanding methods tend to produce either unconstrained results [14], [21] in which walls should be flat bend arbitrarily or planar interpretations [22], [48] in which non-planar objects like lamps are flat. Shape attributes can act as a generic way of representing top-down properties for 3D understanding, sharing with classical attributes the advantage of both learning and application across multiple object classes.

There are two natural questions to ask: what 3D attributes should be inferred, and how to infer them? After further motivating the problem of studying higher order shape in Section 5 we introduce our attribute vocabulary in Section 4 which draws inspiration from and revisits past work in both the computer and the human vision literature. We return to these ideas with modern computer vision tools. In particular, as we describe in Section 6 we use Convolutional Neural Networks (CNNs) to infer the 3D attributes from an image.

A secondary objective of this paper is to obtain a 3D shape embedding – a low dimensional vector representing the 3D shape of the object. Again, this is inferred from an image using a CNN, and described in Section 6. Our aspiration is that the embedding should be largely unaffected by the viewpoint of the image.

The next important question is: what data to use to investigate these properties? We use photos of modern sculptures from Flickr, and describe a procedure for gathering a large and diverse dataset in Section 5. This data has many desirable properties: it has much greater variety in terms of shape compared to common-place objects; it is real and in the wild, so has all the challenging artifacts such as severe lighting and varying texture that may be missing in synthetic data. Additionally, the dataset is automatically organized into: artists, which lets us define a train/test split to generalize over artists; works (of art) irrespective of material or location, which lets us concentrate on shape, and viewpoint clusters, which lets us recognize sculptures from multiple views and aspects.

The experiments in Section 7 show that we are indeed
able to infer 3D attributes. However, we also ask the question of whether we are actually learning 3D properties, or instead a proxy property, such as the identity of the artist, which in turn enables these properties to be inferred. We have designed the experiments both to avoid this possibility and to probe this issue, and discuss this there. Having demonstrated that we can learn to predict 3D shape attributes, Section 8, probes what cues are being used by the network in a process akin to psychophysics.

This paper is an extension of our previous work [20]. The extensions include: (i) additional motivation for our study of higher order shape properties as ends themselves in Section 3; (ii) additional description of experimental details throughout the paper; (iii) more thorough evaluation of the results, such as saliency maps in Section 7.2, and failure modes of the mental rotation task in Section 7.3; and (iv) experiments with synthetic stimuli in Section 8 that provide additional validation that the method is learning about 3D properties, and offer insights into how it uses a mix of shading, contours, and texture.

3 DIRECTLY MODELING HIGHER-ORDER SHAPE

Why should we study higher-order properties of shape as entities in themselves, and not as the result of analyzing a property like a depthmap? In principle, with sufficient resolution and accuracy, a depthmap contains all the information necessary to construct many higher order properties: the normals and curvatures by taking first and second derivatives, and many others by applying the right analysis. It is thus possible that by obtaining a depthmap, one should get higher-order properties for free via this indirect method. While simple, the indirect approach is contradicted by evidence from both humans and machines.

Evidence in psychophysics suggests that the human visual system employs multiple types of representations of shape, and that some properties, which in principle could be derived from depth, are instead obtained directly. Both Koenderink et al. [41] and Norman and Todd [52] found that the accuracy of orientation estimates could be substantially higher than differentiating estimated depth ought to permit. Johnston and Passmore [34] found similar results with orientation and curvature.

The human results of Koenderink et al. and Norman and Todd can be reproduced in machines. Consider the recent approach of [13] that predicts both depth and surface normals from an image with an identical CNN architecture. We can compare the indirect method of computing normals from estimated depth to the direct method of estimating normals using the standard NYUv2 dataset [61] and the...

ground-truth of [44]. While the indirect normals are reasonable, the accuracy still lags far behind the direct method (30.3° vs 20.9° mean error) and is worse in all normal metrics of [21] (and it should be noted that this error gap is probably a best case, since the depth loss of [13] already incorporates a local normal term).

Why might it be the case that the seemingly straightforward notion of obtaining higher-order properties for free indirectly does not lead to good estimates in practice? In addition to pitfalls of all indirect modeling, such as irreversible error accumulation, we outline a few reasons below:

**Direct cues for higher order properties:** One argument in favor of the direct approach is that many “cues for depth”, are actually direct cues for higher order properties, and thus converting them first into cues for depth is suboptimal. Examples include texture gradients [12], [23], which convey changes in surface orientation [19], or the curvature of occluding contours [56], which indicates the sign of the Gaussian curvature of the shape.

**Resolution:** Consider determining if a fence has thin structures or a piece of sandpaper has a rough surface. Compared to simply recognizing wires and bumps, the indirect method requires interpreting the scene at an incredibly detailed resolution – high enough to capture the pixels of the fence wire and sub-millimeter bumps on the sandpaper.

**Ambiguity:** Finally, ambiguities in depth may not be ambiguities for higher order properties, and prematurely resolving them in terms of depth is often the wrong thing to do. For instance, consider observing a surface and having three plausible hypotheses for its shape: convex (z = x²), concave (z = −x²), and flat (z = 0). Suppose one is overwhelmingly confident (> 95% chance) it is not flat but places equal chance on it being the other possibilities. Even though the surface is unambiguously not flat, the correct surface with regards to depth in both the L₁- and L₂-norm sense is a flat surface. If the ambiguity is resolved in depth, the resulting interpretation in terms of higher order properties is radically and incorrectly altered. Instead, if one directly asks whether the curvature is non-zero, the correct answer is obtained.

4 3D Attribute Vocabulary

Which 3D shape attributes should we model? We choose 12 attributes based on questions about three properties of historical interest to the vision community – curvature (how does the surface curve locally and globally?), ground contact (how does the shape touch the ground?), and volumetric occupancy (how does the shape take up space?).

Fig. 2 illustrates the 12 attributes, and sample annotations are shown in Fig. 5, with more in the supplementary material. We now briefly describe the attributes in terms of curvature, contact, and volumetric occupancy.

**Curvature Attributes:** We take inspiration from a line of work on shape categorization via curvature led by Koenderink and van Doorn (e.g., [38]). Most sculptures have a mix of convex, concave, and saddle regions, so we analyze where curvature is zero in at least one direction and look for (1) Has Planarity: piecewise planar sculptures; (2) Has No Planarity: sculptures with no planar regions (note that many sculptures have a mix of planar and non-planar regions); (3) Has Cylindrical: sculptures where one principal curvature is zero (e.g., cylindrical ones); and (4) Has Roughness: rough sculptures where locally the surface changes rapidly.

**Contact Attributes:** Contact and support reasoning plays a strong role in scene understanding (e.g., [25], [26], [30], [32], [61]). We characterize ground contact via (5) Point/line Contact: point or line contact as compared to contact with the full body; (6) Multiple Contacts: whether multiple contacts between the object and the ground are made.

**Volumetric Attributes:** Reasoning about free-space has long been a goal of 3D understanding [30], [47], [56]. We ask (7) Mainly Empty: the fraction of occupied space in the sculpture; (8) Multiple Pieces: whether the sculpture has multiple pieces; (9) Has Hole: whether there are holes (i.e., the topology of the sculpture); (10) Has Thin Structures: whether it has thin structures, irrespective of whether they are sheets or tubular; (11) Mirror Symmetry: whether it has an axis of mirror symmetry in 3D; and (12) Cubic Aspect Ratio: whether it has a cubic aspect ratio in 3D.

Note that of the 12 attributes, 10 are relatively unaffected by a geometric affine transformation of the image (or 3D space) – only the mirror symmetry and cubic aspect ratio attributes are measuring a global metric property.

These are, of course, not a complete set. We do not model, for example, enclosure properties or differentiate a single large hole from a mesh. Similarly, many properties, such as Koenderink and Van Doorn’s shape index or Birdman’s geons are localized or part-based. We leave this to future work.

5 Gathering a Dataset of 3D Shapes

In order to investigate these 3D attributes, we need a dataset of 3D shapes that has a diversity of shape so that different subsets of attributes apply. We use modern sculptures as our source of 3D shapes since they are diverse in form and in-the-wild photos of them are available in great quantities on the Internet.

One alternative would be to use ordinary objects, such as the 20 PASCAL objects [15]. Unfortunately, ordinary objects have limited diversity, not just in terms of overall combinations of shape attributes, but also in terms of shape...
attributes conditioned on category. In practice, this means that if we set out to study shape with ordinary objects, our learning models may simply exploit categories as proxy variables: for example, rather than analyze planarity, our models may take the short-cut of distinguishing people from trains, then predicting planarity accordingly. In contrast, sculpture is free to depict people as planar or objects that defy categorization.

While using modern sculpture helps prevent a trivial solution, artists often produce work in a similar style: Alexander Calder’s sculptures are mostly piecewise planar, Constantin Brancusi’s egg-shaped, and Henry Moore’s (see Fig. 1) are smooth and non-planar. We therefore need a variety of artists and multiple works/images of each. Previous sculpture datasets [2], [3] are not suitable for this task as they only contain a small number of artists and viewpoints. Thus we gather a new dataset from Flickr. We adopt a five stage process to semi-automatically do this: (i) obtain a vocabulary of artists and works (for which many images will be available); (ii) cluster the works by viewpoint; (iii) clean up mistakes; (iv) query expand for more examples from Google images; and (v) label attributes. Note, organization by artist is not strictly necessary. However, artists are used subsequently to split the works into train and test datasets: as noted above, due to an artists’ style, shape attributes frequently correlate with an artist; consequently artists in the train and test splits must be disjoint to avoid an overly optimistic generalization performance. The statistics for these stages are given in Tab. 1.

5.1 Generating a vocabulary of artists and works

Our goal is to generate a vocabulary of artists and works that is as broad as possible. We begin by producing a list of artists, combining manually generated lists with automatic ones, and then expand each artist to a list of their works.

While using modern sculpture helps prevent a trivial solution, artists often produce work in a similar style: Alexander Calder’s sculptures are mostly piecewise planar, Constantin Brancusi’s egg-shaped, and Henry Moore’s (see Fig. 1) are smooth and non-planar. We therefore need a variety of artists and multiple works/images of each. Previous sculpture datasets [2], [3] are not suitable for this task as they only contain a small number of artists and viewpoints. Thus we gather a new dataset from Flickr. We adopt a five stage process to semi-automatically do this: (i) obtain a vocabulary of artists and works (for which many images will be available); (ii) cluster the works by viewpoint; (iii) clean up mistakes; (iv) query expand for more examples from Google images; and (v) label attributes. Note, organization by artist is not strictly necessary. However, artists are used subsequently to split the works into train and test datasets: as noted above, due to an artists’ style, shape attributes frequently correlate with an artist; consequently artists in the train and test splits must be disjoint to avoid an overly optimistic generalization performance. The statistics for these stages are given in Tab. 1.

5.1 Generating a vocabulary of artists and works

Our goal is to generate a vocabulary of artists and works that is as broad as possible. We begin by producing a list of artists, combining manually generated lists with automatic ones, and then expand each artist to a list of their works.

The manual list consists of the artists exhibited at six sculpture parks picked from online top-10 lists, as well as those appearing in Wikipedia’s article on Modern Sculpture. An automatic list is generated from metadata from the 20 largest sculpture groups on Flickr: we analyze image titles for text indicating that a work is being ascribed to an artist, and take frequent bigrams and trigrams. The two lists are manually filtered to remove misspellings, painters and architects, a handful of mistakes, and artists with fewer than 250 results on Flickr. This yields 258 artists (95 from the manual list, and 163 from the automatic).

We now find a list of potential works for each artist using both Wikipedia and text analysis on Flickr. We query the sculptor’s page on Wikipedia, possibly manually disambiguating, and propose any italicized text in the main body of the article as a possible work. We also query Flickr for the artists’ works (e.g., Tony Smith Sculpture), and do n-gram analysis in titles and descriptions in front of phrases indicating attribution to the sculpture (e.g., “by Tony Smith”). In both cases, as in [55], stop-word lists were effective in filtering out noise. While Wikipedia has high precision, its recall is moderate at best and zero for most artists. Thus querying Flickr is crucial for obtaining high quality data. Finally, images are downloaded from Flickr for
TABLE 1
Data statistics at each stage and the trainval/test splits.

| Stage       | Images | Artists | Works | View. Clusters |
|-------------|--------|---------|-------|----------------|
| Initial     | 352K   | 258     | 3412  | --             |
| View Clust. | 213K   | 246     | 2277  | 16K            |
| Cleaned     | 97K    | 242     | 2197  | 9K             |
| Query Exp.  | 143K   | 242     | 2197  | 9K             |
| Trainval/Test| 109K/35K | 181/61 | 1655/532 | 7.2K/2.1K |

5.2 Building viewpoint clusters
Images from each work are partitioned into viewpoint clusters. These clusters are image sets that, for example, capture a different visual aspect of the work (e.g., from the front or side) or are acquired from a particular distance or scale (e.g., a close up). Fig. 3 shows example viewpoint clusters for several works.

There are two principal reasons for obtaining viewpoint clusters: (i) it enables recognition of a work from different viewpoints to be evaluated; and (ii) it makes label annotation more efficient as attributes are in general valid for all images of a cluster. Note, it might be thought that attributes could be labelled at the work level, but this is not always the case. For example, the hole in a Henry Moore sculpture or the ground contact of an Alexander Calder sculpture may not be visible in some viewpoint clusters, so those clusters will be labelled differently from the rest (i.e., no hole for the former, and unknown for the latter).

Clustering proceeds in a standard manner by defining a similarity matrix between image pairs, and using spectral clustering over the matrix. The pairwise similarity measure takes into account: (i) the number of correspondences (that there are a threshold number); (ii) the stability of these correspondences (using cyclic consistency as in [69]); and (iii) the viewpoint change (the rotation and aspect ratio change obtained from an affine transformation between the images). Computing correspondences requires some care though since sculptures often do not have texture (and thus SIFT like detections cannot be used). We follow [1] and first obtain a local boundary descriptor for the sculpture (by foreground-background segmentation and MCG [4] edges for the boundaries), and then obtain geometrically consistent correspondences using an affine fundamental matrix. Finally, a loose affine transformation is computed from the correspondences (loose because the sculpture may be non-planar, hence the earlier use of a fundamental matrix).

In general, this procedure produces clusters with high purity. The main failure is when an artist has several visually similar works (e.g., busts) that are confused in the meta-data used to download them. We also experimented with using GPS, but found the tags to be too coarse and noisy to define satisfactory viewpoint clusters.

5.3 Data Cleanup
The above processes are mainly automatic and consequently make some mistakes. A number of manual and semi-automatic post-processing steps are therefore applied to address the main failings. Note, we can quickly manipulate the dataset via viewpoint clusters as opposed to handling each and every image individually.

Cluster filtering: Each cluster is checked manually using three sample images to reject clearly impure clusters.

Regrouping: Some of the automatically generated works are ambiguous due to noisy meta-data: for instance “Reclining Figure” describes a number of Henry Moore sculptures. After clustering, these are reassigned to the correct works.

Outlier image removal: A 1-vs-rest SVM is trained for each work, using fc7 activations of a CNN [42] pretrained on ImageNet [57]. Each work’s images are sorted according to the SVM score, and the bottom images (∼10K across all works) flagged for verification.

5.4 Expansion Via Search Engines
Finally, we augment the dataset by querying Google. We perform queries with the artist and work name. Using the same CNN activation + SVM technique from the outlier removal stage, we re-sort the query results and add the top images after verification. This yields ∼45K more images.

5.5 Attribute Labeling
The final step is to label the images with attributes. Here, the viewpoint clusters are crucial, as they enable the labeling of multiple images at once. Each viewpoint cluster is labeled
with each attribute, or can be labeled as N/A in case the attribute cannot be determined from the image (e.g., contact properties for a hanging sculpture). One difficulty is determining a threshold: few sculptures are only planar and no sculpture is fully empty. We assume an attribute is satisfied if it is true for a substantial fraction of the sculpture, typically 80%. To give a sense of attribute frequency, we show the fraction of positives in Fig. 4(a).

The dataset is also diverse in terms of combinations of attributes and inter-attribute correlation.

There are \(2^{12} = 4096\) possible combinations, of which 393 occur in our data. Most attributes are uncorrelated according to the correlation coefficient \(\phi\), as seen in Fig. 4(b): mean correlation is \(\phi = 0.13\) and 82% of pairs have \(\phi < 0.2\). The two strong correlations \(\phi > 0.5\) are, unsurprisingly, (1) planarity and no planarity; and (2) emptiness and thinness.

6 Approach

We now describe the CNN architecture and loss functions that we use to learn the attribute predictors and shape embedding. We cast this as multi-task training and optimize directly for both. Specifically, the network is trained using a loss function over all attributes as well as an embedding loss that encourages instances of the same shape to have the same representation. The former lets us model the attributes that are currently labeled. The latter forces the network to learn a representation that can distinguish sculptures, implicitly modeling aspects of shape not currently labeled.

**Network Architecture:** We adapt the VGG-M architecture proposed in [11]. We depict the overall architecture in Fig. 6. All layers are shared through the last fully connected layer, fc7. After fc7, the model splits into two branches, one for each task, the other for embedding. The first is an affine map to 12D followed by independent sigmoids, producing 12 separate probabilities, one per attribute. The second projects fc7 to a 1024D embedding which is then normalized to unit norm.

We directly optimize the network for both outputs, which allows us to obtain strong performance on both tasks. The first loss models all the attributes with a cross-entropy loss summed over the valid attributes. Suppose there are \(N\) samples and \(L\) attributes, each of which can be 1 or 0 as well as \(\emptyset\) to indicate that the attribute is not labeled; the loss is

\[
L(Y, P) = \sum_{i=1}^{N} \sum_{l=1}^{L} Y_{i,l} \log(P_{i,l}) + (1 - Y_{i,l}) \log(1 - P_{i,l}),
\]

for image \(i\) and label \(l\), where we denote the label matrix as \(Y_{i,l} \in \{0, 1, \emptyset\}^{N,L}\) and the predicted probabilities as \(P_{i,l} \in [0, 1]^{N,L}\). The second loss is an embedding loss over triplets as in [53, 59, 66]. Each triplet \(i\) consists of an anchor view of one object \(x_i^n\), another view of the same object \(x_i^p\), as well as a view of a different object \(x_i^n\). The loss aims to ensure that two images of the same object are closer in feature space compared to another object by a margin:

\[
\sum_{i=1}^{N} \max(D(x_i^n, x_i^p) - D(x_i^n, x_i^p) + \alpha, 0)
\]

where \(D(\cdot, \cdot)\) is squared Euclidean distance. We generate triplets in a mini-batch and use soft-margin violaters [58].

![Fig. 6. The multi-task network architecture, based on VGG-M. After shared layers, the network branches into layers specialized for attribute classification and shape embedding.](image)

![Fig. 7. Predictions for all attributes on test images. The system has never seen these sculptures or ones by the artists who made them, but generalizes successfully.](image)

We see a number of advantages to multi-task learning. It yields a network that can both name attributes it knows about and model the 3D shape space implicitly. Additionally, we found it to improve learning stability, especially compared to individually modeling each attribute.

**Configurations:** We explore two configurations to validate that we are really learning about 3D shape. Unless otherwise specified, we use the system described above, Full. However, to probe what is being learned in one experiment, we also learn a network that only optimizes the attribute Loss [1], which we refer to as Attribute-Only.

**Implementation Details:**

**Optimization:** We use a standard stochastic gradient descent plus momentum approach with a batch size of 128. **Initialization:** We initialize the network using the model from [11] which was pre-trained on image classification [57].

**Parameters:** We use a learning rate of \(10^{-4}\) for the pre-trained layers, and \(10^{-3}\) and \(10^{-2}\) for classification and embedding layers respectively. We set the margin \(\alpha\) to 0.1. **Augmentation:** At training time, we use random crops, flips, and color jitter. At test time, we sum-pool over multiple scales, crops and flips as in [11].
7 Experiments

We describe a set of experiments to investigate both the performance of the learnt 3D shape attribute classifiers, and what has been learnt. We aim to answer two basic questions: (1) how well can we predict 3D shape attributes from a single image? and (2) are we actually predicting 3D properties or a proxy property that correlates with attributes in an image? To address (1) we evaluate the performance on the Sculpture Images Test set, and also compare to alternative approaches that first predict a metric 3D representation and then derive 3D attributes from that (Sec. 7.1). We probe (2) in a variety of ways. First, we examine the regions of the image responsible for the predictions in Sec 7.2. Second, we evaluate the learnt representation on a different task – determining if two images from different viewpoints are of the same object or not (Sec. 7.3). Third, we evaluate how well the 3D shape attributes trained on the Sculpture images generalize to non-sculpture data, in particular to predicting shape attributes on PASCAL VOC categories (Sec. 7.4).

Finally, we probe the model with a set of synthetic stimuli in Section 8.

7.1 Attribute Prediction

We first evaluate how well 3D shape attributes can be estimated from images. Here, we report results for our full network. Since our dataset is large enough, the attribute-only network does similarly. We compare the approach proposed in this paper (which directly infers holistic attributes) to a number of baselines that are depth orientated, and start by computing a metric depth at every pixel.

**Baselines:** The baselines start by estimating a metric 3D map, and then attributes are extracted from this map. We use two recent methods for estimating depth from single images with code available: a CNN-based depth estimation technique [14] and an intrinsic images technique [6]. Since [6] expects a mask, we use the segmentation used for collecting the dataset (in Sec. 5.2). One question is: how do we convert these depthmaps into our attributes? Hand-designing a method is likely to produce poor results. We take a data-driven approach and treat it as a classification problem. We use two approaches that have produced strong performance in the past. The first is a linear SVM on top of kernel depth descriptors [9], which convert the depthmap into a high-dimensional vector incorporating depth configurations and image location. The second is the HHA scheme [27], which converts the depthmap into a representation amenable for fine-tuning a CNN; in this case, we learn the attribute network described in Section 6.

**Evaluation Criteria:** Each method produces a prediction scoring how much the image has the attribute. We characterize the predictive ability of these scores with a receiver operator characteristic (ROC) over the Sculpture images test set. This enables comparison across attributes since the ROC is unaffected by class frequency [17]. We summarize scores with the area under the curve.

**Results:** Fig. 7 shows predictions of all of the attributes on a few sculptures. To help visualize what has been learned, we show automatically sampled results in Fig. 8, sorted by the predicted presence of attributes. Additional results are given in the supplementary material.

We report quantitative results in Table 2. On an absolute basis, certain attributes, such as planarity and emptiness, are easier than others to predict, as seen by their average performance; harder ones include ones based on symmetry and aspect ratio, which may require a global comparison across the image, as opposed to aggregation of local judgments.

In relative terms, our approach out-performs the baselines, with especially large gains on planarity, emptiness, and thinness. Note that reconstructing thin structures is challenging even with multi-view stereo as input and typically requires specialized handling [25]. An approach based on depth-prediction is thus likely to fail at reconstruction, and thus on attribute prediction. Instead, our system di-

---

**TABLE 2**

Area under the ROC curve. Our approach achieves strong performance and outperforms the baselines by a large margin.

| Method | Curvature | Contact | Occupancy |
|--------|-----------|---------|-----------|
|        | Plan      | P/L     | Emp       |
| [6] + [9] | 64.1      | 61.1    | 66.5      |
| [14] + [19] | 64.6      | 57.5    | 65.2      |
| [6] + [9] | 70.0      | 63.6    | 73.7      |
| [14] + [19] | 67.5      | 58.5    | 71.5      |
| Proposed | 82.8      | 74.4    | 87.0      |

**Fig. 8.** Test images sampled at the top, 95th, 5th percentiles and lowest percentile with respect to three attributes.
for three attributes. The maps suggest that the network is predicted with AUCS of 80% and previous networks' activations on the test set is high in Section 7.1: the average correlation between the retrained weights by average pooling, thus producing a final feature pooling layer to the conv5 layer. Having done this, we connected layers of our VGG-M network and attach an average × 1

mean increases from 72.3 to 74.4 and 1\(\frac{1}{3}\) of the attributes are predicted with AUCS of 80% or more.

7.2 Saliency Maps

As a way of examining what the network has learned, we use the class-activation mapping (CAM) technique from [68].

Experimental Setup: Using the CAM technique involves connecting the last convolutional layer to the classification weights by average pooling, thus producing a final feature that has as many channels as the convolutional layer but 1 × 1 spatial resolution. We thus remove both fully connected layers of our VGG-M network and attach an average pooling layer to the conv5 layer. Having done this, we retrain the network following identical settings. It should be noted that this produces a different network. However, we found it makes similar decisions to the network trained in Section 7.1: the average correlation between the retrained and previous networks’ activations on the test set is high (0.87); the mean AUC is slightly (0.64%) lower (consistent with results reported for other architectures in [68]), and the maximum deviation of any attribute’s ROC is 3.9%.

Results: We examine saliency by looking at images in the images which cause the top 1K strongest predictions for each attribute in the test set. Fig. 9 shows a selection of these for three attributes. The maps suggest that the network is using the right parts of the image to make its decision, even in the case of confident mistakes (Has Holes, right, which appears to be a hole due to an accidental viewpoint). In the case of analyzing contact, the network appears to be using the place at which “legs” from the sculpture split apart.

We found that the CAM maps localized the sculpture well, suggesting that irrespective of which part is being used, the sculpture itself is driving predictions. To quantify this, we examined segmentation on a set of 40 hand-segmented images. We take the class activation maps for each attribute and normalize them to have the same range, the maps are then averaged over the attributes and treated as a prediction of the sculpture’s segmentation. The predictions achieve an AUROC of 85% against the hand-segmentations.

7.3 Mental Rotation

If we have learned about 3D shape, our learnt representation ought to encode or embed 3D shape. But how do we characterize this embedding systematically? To answer this, we turn to the task of mental rotation [60], [54] which is the following: given two images, can we tell if they are different views of the same object or instead views of different objects? This is a classification task on the two presented images: for instance, in Fig. 10 the task is to tell that (a) and (b) correspond, and that (a) and (c) do not.

Note, the design of the dataset has tried to ensure that sculpture shape is not correlated with location by ensuring that images of a particular work come from different locations (since multiple instances of a work are produced) and different materials (e.g., bronze and stone in Fig. 10).

We report four representations: (i) the 1024D embedding produced by our full network; (ii) the 4096D fc7 layer of the full network; (iii) the 4096D fc7 layer of the attribute-only network; (iv) the attribute probabilities themselves from the full network.

If our attribute network is using actual 3D properties, then the attribute network’s activations ought to work well for the mental rotation task even though it was never trained for it explicitly. Additionally, the attributes themselves ought to perform well.

Baselines: We compare our approach to (i) the pretrained FC7 from the initialization of the network and to (ii) IFV [54] over the BOB descriptor [2] that was used to create the dataset and dense SIFT [19]. The pre-trained FC7 characterizes what has been learned; the IFV representations help characterize the effectiveness of the attribute predictions on their own. We use the cosine distance throughout.
Evaluation Criteria: We adopt the evaluation protocol of [33] which has gained wide acceptance in face verification: given two images, we use their distance as a prediction of whether they are images of the same object or not. Performance is measured by AUROC, evaluated over 100 million of the pairs, of which 0.9% are positives. Unlike [33], positives in the same viewpoint cluster are ignored: these are too easy decisions.

We further hone in on difficult examples by automatically finding and removing easy positives which can be identified with a bare minimum image representation. Specifically, we remove positive pairs with below-median distance in a 512-vocabulary bag-of-words over SIFT representation. This yields a more challenging dataset with 0.3% positives. As mentioned in Sec. 5 artists often produce work of a similar style, and the most challenging examples are often pairs of images from the same artist (which may or may not be of the same work). We call the standard setting Easy and the filtered setting with only hard positives Hard.

Quantitative Results: Table 3 and Fig. 11 show results for both settings. By themselves, the 12D attributes produce strong performance, 3-4% better than IFV representations. The attribute-only network improves over pretraining (by 0.9% in easy, 2.5% in hard), suggesting that it has learned the shape properties needed for the task. The full system does best and substantially better than any baseline (by 3.4% in easy, 6.9% in hard). This is to be expected since Equation 2 modulo a margin parameter, aims to ensure that any positive pair is closer than any negative pair, which is equivalent to the AUROC [17]. Relative performance compared to the initialization consistently improves for both the full system and the attribute-only system when going from Easy to Hard settings, providing further evidence that the system is indeed modeling 3D properties.

Failure Modes: Examining incorrect pairs reveals a number of failure modes that suggest room for further improvement by future work. We define mistakes by converting distances in shape embedding space into classifications by thresholding at the equal error rate point. Figure 12 shows a few illustrative examples of these embedding mistakes; all of the false negatives (i.e., two views of the same sculptures that have high distance) depicted are further apart than all the false positives (i.e., two distinct sculptures that have low distance).

The two most frequent causes of false negative pairs are specular objects that reflect their surroundings and enormous objects that lend themselves to being photographed from a variety of different viewpoints. The most confused object, Anish Kapoor’s Cloud Gate (‘The Bean’) (Fig. 12(b) top) combines both of these. The remaining mistakes are pairs with dramatic scale or viewpoint changes, images where the sculpture is not the salient object, and a handful of labeling errors.

False positive pairs tend to be works by the same artist that or that are similar in terms of properties. The within-artist mistakes tended to be caused by a series of works with a common material and theme, for instance Alexander Calder’s works with red sheet metal (e.g., Fig. 12(a) top). Across artists, the network sometimes had difficulty distinguishing different sculptures made with thin metal structures and between statues of people.

Updated metadata: The above mental rotation experiments are done using the metadata from our prior work [20]. We have since updated the metadata and will release the updates. First, we manually identified works of art in the test set that are of similar shape (i.e., sharing the same attributes) but exactly the same subject (e.g., busts of animals from Ai Weiwei’s Zodiac Heads) and excluded them from mental rotation evaluation. We then trained a CNN on the entire dataset to discriminate between works. Confident prediction mistakes (860) were examined for reassignment frequently confused sculptures (10) were examined for merging or exclusion. In total 7 works and 699 images were updated. Evaluating on this cleaner data leads to an increase in AUROC of about 0.1%; the influence of these updates is limited since the metric is computed over pairs: the updates affect a small fraction of images and an even smaller number of pairs.

7.4 Object Characterization

Our evaluation has so far focused on sculptures, and one concern is that what we learn may not generalize to more everyday objects like trains or cats. We thus investigate our model’s beliefs about these objects by analyzing its
activations on the PASCAL VOC dataset [15]. We feed the windows of the trainval set of VOC-2010 to our shape attribute model, excluding difficult and too-small (< 100px) windows, and obtain a prediction of the probability of each attribute. We probe the representation by sorting class members by their activations (i.e., “which trains are planar?”) and sorting the classes by their mean activations.

Per-image results: The system forms sensible beliefs about the PASCAL objects, as we show in Fig. 13. Looking at intra-class activations, cats lying down are predicted to have single, non-point contact as compared to ones standing up; trains are generally planar, except for older cylindrical steam engines. Similarly, the non-planar dining tables are the result of occlusion by non-planar objects. Per-category results: The system performs well at a category-level as well. Note that averaging over windows characterizes how objects appear in PASCAL VOC, not how they are prototypically imagined: e.g., as seen in Fig. 13, the cats and dogs of PASCAL are frequently lying down or truncated. The top 3 categories by planarity are bus, TV Monitor, train; and the bottom 3 are cow, horse, sheep. For point/line contact: bus, aeroplane, car are at the top and cat, bottle, sofa are at the bottom. Finally, sheep, bird, and potted plant are the roughest categories in PASCAL and car, bus, and aeroplane the smoothest.

Discriminating between classes: It ought to be possible to distinguish between the VOC categories based on their 3D properties, and thus we verify that the predicted 3D shape attributes carry class-discriminative information. We represent each window with its 12 attribute probabilities and train a random forest classifier for two outcomes in a 10-fold cross-validation setting: a 20-way multiclass model and a one-vs-rest. The multiclass model achieves an accuracy of 65%, substantially above chance. The one-vs-rest model achieves an average AUROC of 89%, with vehicles performing best.

8 Analysis by synthesizing stimuli

Interpreting results can be challenging because the cause of two images being interpreted differently could be due to any number of changes between the images. Synthetic data offers an opportunity to systematically analyze a system since it gives an opportunity to ensure only one parameter changes between two images and control that change. In this section, we probe our learned network using a series of renderings in which all underlying factors of the image are tightly controlled. This technique was inspired by past work [71] that probed network response as a function of patch transformations and variations, which in turn was inspired by human psychophysics.

Our goal in this section is complementary to the localization analysis presented in Section 3.2. Our goal here is to systematically model how the network’s response changes as a function of the underlying shape properties of the stimulus; the network localization aims to identify parts of particular images that especially contribute to the final decision. This approach lets us study questions that are practically impossible with real images, such as fixing shape and changing texture or creating shapes that combine cues from two different shapes.

We begin by defining our stimuli, which consist of parameterized deformations of the unit-norm ball. We then test how well the network learned on sculpture can interpret these deformations, providing additional verification that the network has learned the properties of interest. Finally, having defined our stimuli and verified that they are being interpreted correctly, we analyze how sensitive our network is to: cues such as shape and contour, texture variations, and variations in lighting.

8.1 Stimuli

We use three synthetic stimuli consisting of the deformation of a unit-norm ball; each stimulus is parameterized by a single parameter \( p \): (i) \( L_p \): the \( L_p \) ball, \( \{ x \in \mathbb{R}^3 : ||x||_p = 1 \} \). (ii) Noise: the unit sphere with the radius at each vertex additively displaced by a fixed noise pattern generated with fractal Brownian noise. We vary the magnitude of this noise \( p \in [0, 0.5] \). (iii) Oval: A sphere with the \( X \) and \( Z \) axes scaled by a factor \( p \in [1, \frac{1}{L_p}] \). Each tests a different attribute: \( L_p \) tests questions of planarity; Noise test questions of roughness; and Oval tests cubic aspect ratio and thinness.

Each geometry was generated with \( \approx 90K \) vertices and then rendered with a gray specular material under a soft ambient light and a single directional light source using the code of [5]. Finally, each rendering was composited on top of 10 images of open spaces depicting indoor and outdoor spaces and no salient objects. We use multiple backgrounds to preclude effects due to any one particular background (e.g., inadvertent camouflaging).

8.2 Accuracy Experiments

We first verify that the network can interpret these stimuli correctly. In addition to providing additional confirmation that the network has learned the actual properties, any subsequent analysis is useless unless the network interprets the stimuli correctly. We should note that this is not guaranteed: as [53] points out, there is a considerable domain shift between real and synthetic images.
Quantitative criteria: Our stimuli all satisfy the property that increasing a parameter \( p \) increases the presence of an attribute in the shape. We can thus quantify performance by evaluating the correlation between attribute predictions and parameter \( p \). Since the relationship is not necessarily linear, we use Spearman’s rank correlation \( r_s \), which characterizes whether there is a monotonic relationship: 1 indicates perfect rank correlation; 0 indicates no correlation. Since the background alters the predicted attribute, we analyze per-background and report the average across backgrounds.

Results: We show a plot of the predicted shape attributes against the varied parameter \( p \) in Fig. 14, as well as the rank correlation. The black line indicates the average across backgrounds. Directly computing the standard deviation across backgrounds mixes the actual uncertainty with a per-background bias that each background may introduce: the backgrounds with planar textures are viewed as more planar by the network, for instance. We thus compute an updated standard deviation after centering each background’s graph at zero and report 1 standard deviation with a red error bar.

Despite the great dissimilarity between these stimuli and the data on which the model was trained, the network successfully generalizes well and a clear trend emerges in each case. If we repeat the analysis on all the backgrounds pooled together, this trend remains similar, and the rank correlations in each case decrease by an average of only 0.1.

8.3 Analysis Experiments

Now that we have demonstrated that the network’s response to stimuli are accurate, we analyze the responsible factors. Our results show that the network is simultaneously incorporating a variety of signals ranging from mathematically-modelable shape cues such as shading and contours to data-driven correlations between shape, color, and texture. We focus on planarity due to the large literature on curvature perception (e.g., [7], [34], [38]).

Results with conflicting cues: There are a variety of cues by which people and machines can see 3D, so an important question is how the network is doing it. For instance: the results on PASCAL showed that a network trained on sculptures could accurately identify non-planar trains. It is not clear, however, what cues were used.

The synthetic stimuli let us analyze this question via composite objects that have conflicting cues, similar to cue combination techniques used in human subjects [10], [50], [51], [67]. Here, we use this to analyze the role of contour and shading cues in predicting the planarity of an object by creating objects that combine the contours and shading cues of a sphere and cube – for instance, a sphere that has the occluding contour of a cube. By shading, we mean the change in intensity caused by the projection of the light onto a particular shape. We show some examples of these objects in Fig. 15; each column depicts a fixed shading (row) or occluding contour (column); the original stimulus goes...
along the diagonal. In the original stimulus, the cues were varied jointly, but we can also fix one cue and vary the other.

Both cues are being used by the network, but shading cues appear to dominate contour ones. We quantify this by correlation and range of responses: if a cue is being used, the perceived planarity should be correlated with the change in cue (i.e., more planar contours produce more planar perceptions); the range of values taken when a cue is varied indicates how heavily the cue is used. We show both metrics in Table 4 in the case where we vary one or more cues. It can be seen that: both cues are used; the strongest response occurs when both are varied at the same time; and if only shading produces a far stronger response than contour. We also found that the contour cue was inconsistent in its effectiveness across backgrounds, presumably due to varying difficulty in finding the precise contour.

**Sensitivity to Light:** If shading cues are important for interpreting shape, then it may be sensitive to the lighting conditions. Here, we experimentally examine this with a set of 100 lighting setups. These have randomized count (1–6), locations, and colored intensities; results are similar with grayscale lighting, but lower variance in general.

One way to evaluate how sensitive the network is to lighting is to quantify how lighting and predicted planarity vary together. For instance, ideally we ought to see the same strong correlation between underlying shape and predicted shape, even under extreme and unrealistic lighting. We find this to be true: for fixed background and lighting, there is still an average 0.9 rank correlation between the predicted and actual shape; occasional failures happen with harsh overexposing lighting that obscures details. Similarly, if we fix the input stimulus, we ought to see little variance as we change the lighting. Unambiguous stimuli (octahedra/spheres/cubes) were interpreted consistently: the standard deviation across the lightings ranges from 0.06 to 0.08 on these stimuli (as reference the difference between the average cube and sphere interpretation is 0.7). Ambiguous stimuli had a higher variance, but all had standard deviations below 0.21.

An important case are catastrophic errors where lighting radically changes shape interpretation. We quantify this by examining how frequently octahedra and cubes were predicted as less planar than spheres. This never occurred when lighting was set identically for the stimuli. Changing lighting independently for the two stimuli cause mistakes in a handful (37) of cases out of the 200K possible pairs (< 0.02%). Most were caused by lighting hiding one stimulus and revealing the other (e.g., green light on one stimulus and deep purple on another, both in front of green hills).

### Sensitivity to Texture:

We next examine whether the network has learned any correlations between texture and shape. We try six texture options: (1) None, the original material; (2) Dots, randomized ellipses; (3) Brownian, fractal Brownian noise; (4) Marble, which is the Brownian stimulus histogram equalized, which yields a marble-like effect; (5) Wood; and (6) Leopard print. Dots tests a simple synthetic stimuli; Brownian and Marble are useful since they are simple transformations of each other; Wood and Leopard test textures that are not simple mathematical processes.

We show the six stimuli and the response curve, averaged over backgrounds, for each texture on the $L_p$, $p \in [1, 2]$ stimulus in Figure 16. First, we note that, just as in the case of lighting variations, the network still produces the correct response to the stimulus for any particular texture: the average rank correlation between perceived geometry and underlying geometry is 0.96. Second, the differences between the curves suggest that the network has learned to exploit correlations between texture and shape: for instance, simply histogram-equalizing the Brownian stimulus to make it look like marble changes the overall likelihood of planarity. Together, these demonstrate that the network factors in natural correlations between texture and shape, but is not completely controlled by it.

### 9 Summary and Extensions

We have shown that 3D shape attributes can be inferred directly from images at quite high quality. In the process, we have introduced a large dataset of modern sculpture for analyzing 3D shape attributes, verified that our learned models are actually inferring the attributes and not a proxy property and analyzed what cues are being used to infer these attributes.

One application is to use the attributes to help constrain metric reconstruction. There has been considerable work recently on using categories to constrain or regularize reconstruction [28], [35], [45] – for example roads and walls should be planar but people should not be – and 3D shape attributes can be used similarly. In contrast to categories, though, attributes offer a number of advantages: they can handle unseen categories, or the open world problem; they enable sharing across categories during learning; and they handle exceptions more easily – some walls and many roads are not, in fact, planar.
Another area of investigation is extending our shape attributes beyond global, absolute properties. One way is explicitly formulating our problem in terms of relative attributes: many of our attributes (e.g., planarity) are better modeled in relative terms. An orthogonal direction is by parsing objects both globally as well as locally. For instance one could describe a sculpture as being primarily rough, but also localize its small smooth regions.
