INTRODUCTION

Autism-spectrum disorder (ASD) is a neurodevelopmental disorder characterised by repetitive or stereotyped behaviours, and deficits in social relationships. Although ASD is a highly heritable disorder, several candidate environmental risk factors have been identified such as prenatal and early life exposures related to infection, obstetric complications and toxin-related exposures. Another potential environmental risk factor for ASD is gestational vitamin D deficiency. The vitamin D system is best known for its role in calcium signalling, neurotrophic and neuroprotective actions, as well as its role in neuronal differentiation, maturation and growth.

There is a growing body of evidence linking gestational vitamin D deficiency with neurodevelopmental disorders such as schizophrenia and ASD. Birth cohort studies have provided evidence that gestational vitamin D deficiency (based on prenatal maternal sera) is associated with impairment on a range of cognitive outcomes related to language, motor development and general intelligence. With respect to autism-related traits, an Australian birth cohort study reported an association between lower mid-gestation 25-hydroxyvitamin D (25OHD) concentrations and higher scores on the Attention Switching subscale of the Autism-Spectrum Quotient.

Although several studies have assessed vitamin D status in children with ASD and one study has compared neonatal vitamin D status in those with ASD versus their unaffected sibling, to the best of our knowledge, no studies have examined the association between gestational vitamin D deficiency and autism or autism-related traits in general population samples.

ASD can be conceptualised as a pronounced and disabling mix of autism-related traits that also exist in a continuum (from mild to severe) in the general population. As healthy individuals vary substantially in their capacities for social-emotional interactions and communications, these autism-related traits are thought to follow a normal distribution within the general population. Family studies have shown an increase in autism-related traits in relatives of individuals diagnosed with ASD, suggesting that the same genetic factors affect both ASD and autism-related behaviours. Epidemiological studies have suggested a shared aetiology for autism-related traits in the general populations and at the quantitative extremes. Recently, Robinson et al. have shown that genetic influences on ASD risk also influence typical variation in the population in autism-related traits such as social-emotional interaction and communication ability, suggesting that ASD-related phenotypes can be studied in a quantitative manner.

To this end, we have explored the association between gestational 25OHD concentrations and a widely used parent-report continuous measure of autism-related traits—the Social Responsiveness Scale (SRS). We had the opportunity to do so in a large multi-ethnic population cohort where vitamin D concentrations were available at two time points: at mid-gestation and at birth.

There is intense interest in identifying modifiable risk factors associated with autism-spectrum disorders (ASD). Autism-related traits, which can be assessed in a continuous fashion, share risk factors with ASD, and thus can serve as informative phenotypes in population-based cohort studies. Based on the growing body of research linking gestational vitamin D deficiency with altered brain development, common exposures are a candidate modifiable risk factor for ASD and autism-related traits. The association between gestational vitamin D deficiency and a continuous measure of autism-related traits at ~6 years (Social Responsiveness Scale; SRS) was determined in a large population-based cohort of mothers and their children (n = 4229). 25-hydroxyvitamin D (25OHD) was assessed from maternal mid-gestation sera and from neonatal sera (collected from cord blood). Vitamin D deficiency was defined as 25OHD concentrations less than 25 nmol l⁻¹. Compared with the 25OHD sufficient group (25OHD > 50 nmol l⁻¹), those who were 25OHD deficient had significantly higher (more abnormal) SRS scores (mid-gestation n = 2866, β = 0.06, P < 0.001; cord blood n = 1712, β = 0.03, P = 0.01). The findings persisted (a) when we restricted the models to offspring with European ancestry, (b) when we adjusted for sample structure using genetic data, (c) when 25OHD was entered as a continuous measure in the models and (d) when we corrected for the effect of season of blood sampling. Gestational vitamin D deficiency was associated with autism-related traits in a large population-based sample. Because gestational vitamin D deficiency is readily preventable with safe, cheap and accessible supplements, this candidate risk factor warrants closer scrutiny.

Molecular Psychiatry (2018) 23, 240–246; doi:10.1038/mp.2016.213; published online 29 November 2016
The cohort

This study was embedded in the Generation R Study, a population-based prospective cohort from fetal life onward, based in Rotterdam, The Netherlands. The design and cohort of Generation R is extensively described elsewhere. In brief, the study was designed to identify environmental and genetic correlates of normal and abnormal health-related outcomes in mothers and their children. A total of 9778 mothers were enrolled in the study, of these mothers, 8878 (91%) enrolled during pregnancy. Delivery date of the pregnant women was between April 2002 and January 2006. Cohort retention until the age of 6 years, the age of SRS measurement, exceeded 80%.

Generation R is a multi-ethnic cohort with the Dutch comprising roughly half of the sample. The ethnic background of the children was defined by the parents’ country of birth, and further classified using definitions from Statistics Netherlands. If both parents were born abroad, the country of birth of the mother was used to define the child’s ethnicity. The main non-Dutch ethnic groups were Surinamese, Turkish, Moroccan and Cape Verdian, which together accounted for almost 30% of the cohort. Written informed consent was obtained from the mothers, and the study was approved by the institutional review board of the Erasmus Medical Centre.

Vitamin D status

Vitamin D status was assessed by measuring the storage form 25OHD. Samples were quantified using isotope dilution liquid chromatography-tandem mass spectrometry. The analytical system consisted of a Shimadzu Nexera UPLC coupled to an AbSciex 5500 QTRAP equipped with an APCI source. Assay accuracy was assessed using certified reference materials purchased from the National Institute of Standards and Technology (NIST SRM 972a Levels 1–4). Further details of the assay methodology can be found in the Supplementary Material (Supplementary Methods 2).

The prevalence and socio-demographic correlates of 25OHD concentrations in the Generation R cohort have been described extensively elsewhere. 25OHD concentration was defined as the sum of 25-hydroxyvitamin D3 (25OHD3) and 25-hydroxyvitamin D2 (25OHD2) species measured in serum. 25OHD was measured from prenatal and cord serum in a total of 7935 expecting mothers and their children. The first sample was taken at mid-gestation: “mean (s.d.) gestational age 20.6 (1.2) weeks, range 18.1–24.9 weeks”. The second sample was collected at birth, from neonatal cord blood: “mean (s.d.) gestational age 40 (1.5) weeks, range 28.4–43.6 weeks”.

The relationships between 25OHD concentrations and various health-related outcomes can be non-linear. Although there is some debate about the definition of deficiency and insufficiency with respect to different health outcomes, there is widespread agreement that concentrations lower than 25 nmol l\(^{-1}\) can be defined as deficient (and associated with increased risk of adverse health outcomes). In keeping with recommendations for thresholds as defined by the Institute of Medicine, we examined three stratified levels of 25OHD concentrations: deficient \((<25.0 \text{ nmol l}^{-1})\), insufficient \((25.0–49.9 \text{ nmol l}^{-1})\) and sufficient \((50 \text{ nmol l}^{-1} \text{ or more})\). We also examined the association between 25OHD concentrations when assessed as a continuous variable. Because the fetus is entirely dependent on the maternal supply of vitamin D, and because of the relatively long half-life of 25OHD (approximately 2 weeks), cord blood assays serve as a proxy measure of late gestational vitamin D status (with deficient cord levels suggesting a vitamin D-deficient environment during late gestation). 25OHD concentrations in maternal serum collected at delivery and neonatal cord blood are highly correlated \((r \approx 0.7)\).
Imputation was performed using the ‘Mix’ imputation package in R.50 ‘Mix’ uses an iterative multiple regression algorithm, which is Expectation-Maximisation based and imputes mixed continuous and categorical data under the general location model. Imputation expectancies were based on covariates only and were independent of predictor variables (25OHD concentrations) and outcome variable (SRS). Four out of eight variables covariates only and were independent of predictor variables (25OHD under the general location model. Imputation expectancies were based on Maximisation based and imputes mixed continuous and categorical data.

Main analyses

Within a linear model framework, we first compared SRS scores between those with (a) deficient versus sufficient and (b) insufficient versus sufficient concentrations of vitamin D, for both mid-gestation and cord blood. Parental and offspring variables were included as covariates in the model. Second, we compared SRS scores between those who were deficient at two time points (mid-gestation and cord blood) and those that were not deficient at either time point and we compared SRS scores between those that were deficient at one time point (mid-gestation or cord blood) and those that were not deficient at either time point. Third, we tested the association between continuous measures of vitamin D and SRS. In addition, we tested whether vitamin D deficiency was predictive of SRS when SRS was treated as a dichotomous outcome. In this analysis, the outcome variable was high-SRS for those children with SRS scores above the suggested gender-weighted cutoff and low-SRS for those with scores below the cutoff.

Sensitivity and responder analyses

In addition to the main analyses, we undertook three planned sensitivity analyses. First, we analysed only offspring with European ethnic background. Second, we replaced the ethnicity variable with a genetic component that captures both population stratification and family-relatedness and allows a test for association that is free from confounding owing to sample structure. In this setting, we do not want to adjust the analyses based on any particular single-nucleotide polymorphism, but for an overall, genome-wide degree of relatedness. Third, we adjusted the models for season of blood sampling to (a) correct for within-year fluctuations in 25OHD concentrations and (b) to reduce the influence of other (unobserved) seasonally fluctuating exposures. A detailed description of the models is provided in the Supplementary Material, including both a simplified ‘worked example’ and a detailed technical description of the Genetic Relationship Matrix approach for dealing with sample structure. In our prospective population cohort we have missingness on socio-demographic variables, blood samples and SRS. We compared SRS responders versus non-responders in order to explore the impact of attrition/missingness on key socio-demographic variables.

RESULTS

Supplementary Figure 1 depicts a flow chart of the inclusion of participants in this study. In total, 4229 children and their mothers were available with measures of vitamin D concentrations drawn from maternal blood at mid-gestation and/or drawn from cord blood at time of birth as well as data on the SRS, 2489 children and their mothers were available with measures of vitamin D concentrations at both time points. Of the 4229 children in our sample, 3169 of the children had individual level genotype data available. Table 1 provides an overview of the distributions of parental and offspring demographic variables before and after imputation.
Table 2. Prevalence of deficiency in mid-gestation and cord 25OHD samples

Abbreviations: 25OHD, 25-hydroxyvitamin D; BMI, body mass index. Notes: Panel A: One time-point analyses: association between 25OHD deficiency and Social Responsiveness Scale (SRS) for 25OHD categories from mid-gestation and neonatal samples; Panel B: Two time-point analyses: association between mid-gestation and cord 25OHD deficiency and SRS; Panel C: 25OHD analyses as a continuous measure; for all analyses presented in Panel A, B, and C, estimates are based on a mixed linear model; family membership was fitted as a random effect in the model; N = sample size, β = effect size; s.e. = standard error; χ²(1) = chi-squared test statistic with 1 degree of freedom; P = P-value; *significant at α of 0.05; **significant at α of 0.01; ***significant at α of 0.001; covariates included in the model are: ethnicity of child; sex of child, age child at time of SRS assessment, birth weight child, gestational age at time of birth, age mother at intake, age father at intake, smoking mother during pregnancy, educational level mother and BMI mother at mid-gestation. For the analyses presented in Panels A and B, that is, 25OHD concentrations are categorised into three categories: sufficient, insufficient and deficient, positive beta values imply an association between more deficient categories of 25OHD concentrations and increase (more impaired) scores on the SRS; For the analyses presented in Panel C, that is, 25OHD concentrations are treated as continuous measures in the analyses, negative beta values imply an association between lower concentrations of 25OHD and increased (more impaired) scores on the SRS; 25OHD concentrations ≥ 5 s.d.s above the mean were winzorised, this is 25OHD > 150 nmol l⁻¹ for mid-gestation samples (n = 4) and 25OHD > 100 nmol l⁻¹ for Cord samples (n = 20). 25OHD measures were log-transformed; results of statistically significant analyses (α < 0.05) are presented in bold font.

Table 2 summarises the prevalence of 25OHD deficiency in mid-gestation and cord blood for those samples for which SRS scores were available. The proportion of the sample with deficiency was substantial: 16% for maternal serum at mid-gestation and 36% for cord blood. On average, 25OHD concentrations from cord blood were lower compared with concentrations at mid-gestation (mean 25OHD concentration in maternal serum at mid-gestation: 58.9 nmol l⁻¹; mean 25OHD concentration in cord blood: 35.9 nmol l⁻¹; t = 35.8, P < 0.001).

Vitamin D and SRS scores

Scores on the SRS were available for 4229 children. The data were right skewed and in order to improve the distribution of the outcome variable, values for the SRS were ‘winsorized’ (that is, extreme outlier scores were recoded to improve distribution). Scores higher than 1.5 (corresponding with ~ 2.5 s.d.s above the mean, n = 21 children) were set to equal 1.5. Supplementary Figure 2 depicts the distributions of the raw SRS scores and the gender-weighted and winsorized SRS scores. Mean gender-weighted scores (s.d., range) of the SRS was 0.23 units (0.23, 0–1.5) and median (interquartile range) of 0.17 (0.06, 0.29). Mean SRS (s.d.) for individuals vitamin D deficient, insufficient and sufficient at mid-gestation was: 0.32 (0.28), 0.24 (0.24) and 0.20 (0.20), respectively. Mean SRS (s.d.) for individuals vitamin D deficient, insufficient and sufficient based on cord blood was: 0.27 (0.25), 0.21 (0.22) and 0.19 (0.20), respectively. Supplementary Table 3 also provides an overview of the SRS scores for different vitamin D deficiency categories.

Table 3 shows the results of the main analyses for the SRS (including ethnicity as a covariate). In all analyses, 25OHD deficiency or lower 25OHD concentrations were associated with higher (more impaired) SRS scores. Compared with those who were sufficient, those who were deficient at mid-gestation or deficient at time of birth were significantly more likely to have higher SRS scores (mid-gestation: β = 0.06, s.e. = 0.01, P < 0.001; cord: β = 0.03, s.e. = 0.01, P = 0.01). Moreover, compared with those who were sufficient at mid-gestation, those who were insufficient were also significantly more likely to have higher SRS scores (β = 0.02, s.e. = 0.01, P = 0.007) (see Table 3A). These results imply that, after correcting for confounding variables (see notes under Table 3), those who were deficient at time of birth had on average 0.06 point higher gender-weighted SRS score, which corresponds to an increase of approximately one fourth of the s.d. (s.d. of the SRS in the total sample = 0.23). When treating SRS as a dichotomous outcome, that is, comparing children with SRS scores above the suggested cutoff with children below the suggested cutoff, those who were vitamin D deficient at mid-gestation were 3.8 times more likely to be screened positive than those who were vitamin D sufficient at mid-gestation (see also Supplementary Table 4).
The comparison of SRS scores of those that were deficient at two time points (mid-gestation and cord blood) versus those that were not deficient at either time point showed that being 25OHD deficient at both time points was predictive of higher SRS scores. Having 25OHD deficiency at only one time point (mid-gestation or cord blood) did not predict SRS scores (Table 3B). When we treated 25OHD concentrations as continuous variables we observed a significant increase in SRS scores with decreasing concentrations of 25OHD for both mid-gestation and cord samples, that is, a similar pattern as observed in the association between vitamin D deficiency categories and SRS (Table 3C).

Sensitivity and responder analyses

In the analyses restricted to offspring with European ethnicity, we found that the pattern of findings persisted with significant increase in SRS scores for those deficient versus sufficient (both Midgestion and Cord) and for those insufficient vs sufficient (mid-gestation) (Supplementary Table 5). Similarly, when we replaced ethnicity with the genetic component that captures both population stratification and family-relatedness, the pattern of findings identified in the main analyses persisted, suggesting that the observed association was free from confounding with ethnicity (Supplementary Table 6). The results persisted after adjusting the models for season of blood sampling (that is, season at mid-gestation or at time of birth for respective analyses). Results shown in Supplementary Table 7. Those who dropped out, or had missing data for the predictor and/or outcome variable, were more likely to have the follow characteristics; (a) non-European, (b) less well educated, (c) smoked during the pregnancy, (c) younger parental age and (d) shorter gestational age. There was no significant difference in the gender of the child (Supplementary Table 8).

**DISCUSSION**

In our population-based cohort study sample of 4229 children, we show that gestational vitamin D deficiency was associated with higher scores on the SRS. We report for we believe the first time an association between mid-gestational 25OHD deficiency and variation in a widely used, continuous measure of autism-related traits in the general population. The pattern of findings persisted when we restricted the analyses to the offspring of European ethnicity and when we accounted for sample structure using individual level genetic data of the offspring. These analyses strongly reduce the chance that our main analyses were confounded by ethnic diversity within the sample.

When we examined the two time-point measures of vitamin D deficiency we found only mother-infant pairs with deficiency at both time points had higher scores on the SRS. This finding suggests that infants exposed to persistent low vitamin D from mid-gestation until birth may be at risk for autism-related traits, whereas this was not identified in those with deficiency at only one time point. In light of the (a) significant relationship between 25OHD when assessed as a continuous variable versus SRS, and (b) the significant relationship between both mid-gestation deficient and insufficient 25OHD concentration versus SRS, we speculate that the exposure may operate as a continuous graded risk factor, without a critical threshold. Our study, based on a large, population-based, multi-ethnic cohort, was well suited to test our hypotheses. The prevalence of vitamin D deficiency was high (16% of the mothers had mid-gestational 25OHD concentrations < 25 nmol L⁻¹; based on cord blood, the prevalence of vitamin D deficiency was 36%).

Vitamin D is a fat-soluble vitamin that, in humans, is obtained from exposure to sunlight and, to a lesser extent, from diet. The active form of vitamin D (1,25 dihydroxyvitamin D) binds to the vitamin D receptor, which is a member of a phylogenetically conserved superfamily of nuclear receptors. Several other ligands operating via nuclear receptors are known to be important in brain development (for example, retinoic acid, glucocorticoids, thyroid hormone, sex hormones). Both the vitamin D receptor and the rate-limiting enzyme required for the production of 1,25 dihydroxyvitamin D, are expressed in neurons and glial cells in the brain. 

The findings from the current study lends weight to the growing body of research linking gestational vitamin D deficiency and altered brain development. Rodent models based on transient prenatal exposure to vitamin D deficiency have found a range of persistent molecular (gene and protein expression), neurochemical and behavioural changes of interest to neuropsychiatry.

Neonatal vitamin D deficiency has been previously associated with an increased risk of schizophrenia, and ASD and schizophrenia are known to share genetic risk variants. Our findings provide additional evidence of the shared risk architecture between these two neurodevelopmental disorders. These convergent clues may provide insights into the etiopathogenesis of neurodevelopmental disorders. For example, the active form of vitamin D (1,25 dihydroxyvitamin D) is known to impact on the function of voltage-gated calcium channels. Variants in genes coding for subunits of these same calcium channels (for example, CACNA1C) have been linked to both schizophrenia and ASD. In addition, vitamin D has been linked to other neurobiological features associated with autism. For example, 1,25 dihydroxyvitamin D has been shown to influence the expression of tryptophan hydroxylase 2 (a key enzyme in the production of serotonin). Mice exposed to adult vitamin D-deficient diets had altered behaviour (that is, hyperlocomotion in a novel open field) and a significant reduction in the key enzyme involved in the key synthesising enzymes for GABA, glutamic acid decarboxylase type 65 and 67 (GAD65, GAD67). Reductions in the expression of GAD65/67 has been previously reported in post-mortem studies of ASD.

With respect to study limitations, although we had measures of 25OHD concentrations at two developmental time points, we lacked information at other stages of gestation and early life. Defining the precise critical window during which developmental vitamin D deficiency adversely impacts on brain development would be premature. Differential attrition is known to impact on the representativeness of modern birth cohorts. Several of the variables associated with non-responder status in our study are associated with either low vitamin D (for example, non-European ethnicity, smoking), and/or risk of autism-related outcomes (for example, lower gestational age). In the presence of a true association between gestational vitamin D deficiency and higher SRS scores, this differential pattern of nonresponse would bias the sample toward the null hypothesis (it is therefore unlikely that the observed responder bias could account for our significant findings). It should also be noted that we do not believe that low gestational 25OHD concentration is solely linked to higher scores on the SRS (that is, specificity between the exposure and the outcome). There is evidence linking low prenatal vitamin D status with increased risk of other neurodevelopmental disorders such as schizophrenia and attention deficit and hyperactivity disorder. Although the SRS is well suited to assess autism-related traits, poor communication can also be associated with a range of other childhood disorders. Findings based on observational epidemiology are susceptible to residual confounding and it is feasible that vitamin D status could serve as a proxy marker for other (unobserved) risk-modifying factors linked to SRS scores. Randomised controlled trials of vitamin D supplementation during pregnancy will be needed in order to confidently link vitamin D and an increased risk of autism-related conditions. In light of the evidence linking prenatal vitamin D with general growth and bone health such trials should be designed with several primary outcomes. In our data, we observe a more pronounced association for those who were deficient at two time points (that is, mid-gestation and at time of birth) compared with deficiency at
only one time point. We also detected an association between the continuous measure of vitamin D concentrations and autism-related traits, letting us hypothesise that vitamin D is operating as a continuous grade risk factor without a critical threshold. Randomised controlled trials will be required to test this hypothesis.

Future research should focus on specificity of the effect of early life vitamin D deficiency in relation to neurodevelopmental disorders. Alongside animal studies that aim to elucidate the biological mechanisms linking vitamin D deficiency and brain development, human studies could focus on endophenotypes to better understand the pathway from vitamin D deficiency to various neurodevelopmental disorders (for example, structural and functional magnetic resonance imaging\textsuperscript{64,231}).

This study has several important strengths. Our sample was based on a large representative multi-ethnic cohort. We used a gold standard assessment of 25OHD concentrations, and a widely used measure of autism-related traits. We had access to infant genotypes and were able to explore innovative models that can more precisely adjust for ancestral differences and family-relatedness in the cohort.

Our findings require replication in independent samples. We are aware of several case–control studies currently underway that will examine the association between neonatal 25OHD and ASD. Ideally, future studies should examine additional time points during gestation, as well as cord/neonatal samples, as it remains to be determined whether gestational and early life vitamin D status has a ‘critical window’ when the brain is differentially sensitive to this exposure.

**CONCLUSIONS**

25OHD deficiency assessed either at mid-gestation or at birth was associated with an increase in autism-related traits in 6-year-old children. The association between developmental vitamin D deficiency and autism-related traits may have important implications from a public health perspective. It is feasible that a safe, cheap and publicly accessible vitamin D supplement in at-risk groups may reduce the prevalence of this risk factor. Just as prenatal folate supplementation has reduced the incidence of spina bifida, we speculate that prenatal vitamin D supplementation may reduce the incidence of ASD.
