Abstract

**Background:** Adenovirus pneumonia account for 5%-10% of respiratory tract infections in children. However, it is rarely observed in immunocompetent patients. We sought to describe clinical and CT characteristics of community-acquired Adenovirus pneumonia in immunocompetent adults.

**Methods:** 20 patients with clinically diagnosed adenovirus pneumonia from two hospitals were retrospectively included from January 2018 to December 2019. Medical records and chest CT of all patients were reviewed and summarized.

**Results:** A total of 20 patients who were consisted of 18 men and 2 women with a median age of 36 years-old (range, 18-48). The clinical findings of patients with adenovirus pneumonia is high fever (>39°C) with the normal white blood cell (WBC) count and decreased Lymphocyte and elevated C-reactive protein. 10 cases complicated with mycoplasma infection when admission. Staphylococcus epidermidis was found in blood culture of 2 patients. CT findings included consolidation in all patients, ground glass opacity (GGO) in 13 patients, and pleural effusion in 12 patients. 13 patients were mechanically ventilated and 2 patients died during hospitalization.

**Conclusions:** The most frequent finding of adenovirus pneumonia on CT was consolidation in the early stage. In adult patients with high fever, normal WBC count and decreased Lymphocyte, consolidation with/without GGO in the early stage may be a clue for suspecting adenovirus pneumonia.

**Background**

Adenovirus is a double-stranded DNA virus widely distributed in nature. It is mainly transmitted through the respiratory tract, causing not only upper respiratory tract infections but also pneumonia[^1]. Adenovirus pneumonia is more common in children under 5 year old and immunocompromised people[^2, 3] and may progresses rapidly to severe pneumonia, acute respiratory distress syndrome, and even death. Previous studies of adenovirus pneumonia in immunocompetent adults mostly focused on outbreaks and epidemics of adenoviral pneumonia in military camps, schools, and medical institutions[^4]. In recent years, the incidence of immunocompetent adults has gradually increased and was reported to account for 1-7% of adult respiratory infections[^4]. However, most cases are reported
sporadically while the clinical and radiological reports of adult community-acquired adenovirus pneumonia was limited \cite{5}. The purpose of the present study was to summary clinical and CT characteristics of community-acquired adenovirus pneumonia in immunocompetent adults.

**Methods**

**Study population**

The study protocol was approved by the institutional ethical review board. Informed consent was waived because this was a retrospective study. Patients with adenovirus pneumonia at China-Japan hospital and Beijing Chaoyang hospital from January 2018 to December 2019 were retrospectively included. All the patients were diagnosed by a positive nucleic acid detection for adenovirus in bronchoalveolar lavage fluid (BALF). Medical records of all patients were reviewed to obtain the clinical data of the patients, including age, sex, symptoms, laboratory and etiological findings, clinical course, and survival outcome et al. Patients who underwent in-patient CT were included. Patients who were younger than 18 years old were excluded.

**Chest CT and analysis**

Thoracic CT were performed (Canon CT\textsuperscript{\textregistered}Aquilion one and Simens, SOMATOM Definition Dual Source CT, Germany) in two imaging centers using parameters as follow: calibration, 0.5mm x 80mm, tube voltage, 120kVp; Automatic modulation tube current; 5.0 mm slice thickness with 5.0 mm gap and 1.0 mm slice thickness with 1.0 mm gap (the latter was used for multiple planar reconstruction). Imaging characters were evaluated by 2 experienced radiologists in consensus.

**Statistical analysis**

Statistical analysis was performed on SPSS (version 20.0, IBM Corp., Armonk, NY, USA). Continuous variables were expressed as median with interquartile range (IQR) and compared by Mann-Whitney U test, and categorical variables as number (proportion) and compared by chi-square test or Fisher’s exact test. All of those were two-sided test, P<0.05 was considered statistically significant difference.

**Result**

**Clinical characteristics**

A total of 20 patients who were consisted of 18 men and 2 women with a median age of 36 (range, 18-
48) years were included. Clinical characteristics of these patients were summarized in Table 1. The symptoms and signs on admission include fever (n=20, 39.2±0.80°C), dry cough (n=6), diarrhea (n=6), sore throat (n=4), dyspnea (n=6), pharyngeal congestion (n=6), moist/dry rales (n=13) and myalgia (n=20). Moreover, no patient presented with tonsil enlargement, conjunctivitis or lymphadenopathy. 10 cases complicated with mycoplasma infection and Staphylococcus Epidermidis was found in blood culture of 2 patients when admission. 14 patients took oral antibiotics before admission. An average smoking time of 12 patients was 4±2 years. The median duration of symptom onset prior to the hospital admission was 6 days (IQR, 3-8 days). 13 patients required mechanical ventilation among whom 11 patients were mechanically ventilated as soon as they were admitted to the hospital and 2 patients were mechanically ventilated within 2 days due to the rapid decrease in partial oxygen pressure after admission. 7 patients had no mechanical ventilation during hospitalization. The median length of hospital stay was 17 days (IQR, 12-33 days) while 2 patients respectively died in 7 days and 11 days after admission. Figure 1 demonstrated the season distribution of adenovirus pneumonia onset and the months with the highest incidence were August, and then February.

**Laboratory findings**

Baseline laboratory findings of patients on admission were demonstrated in the table 2. The median total WBC counts, median platelet count, cholinesterase were in normal levels, the median Lymphocyte percentage and PO2 decreased while the median neutrophil percentage, C reaction protein, procalcitonin (PCT), LDH and CK levels elevated.

Table 3 showed there was no statistically significant difference in the neutrophil percentage and PO2 between patients with and without mycoplasma infection. Moreover, no significant difference was observed in PO2 between patients with and without mechanical ventilation. However, patients with mechanical ventilation had a higher neutrophil percentage than patients without mechanical ventilation (p=0.001)

**CT findings of Adenovirus Pneumonia**
Initial CT findings of adenovirus pneumonia were indicated in table 4 and 5. The predominant CT findings were consolidation (100%) and Ground-glass opacity (GGO) (65%), which was unilateral or bilateral peribronchovascular and central distribution. Segmental consolidation of patients (70%) diffusely distributed in the bilateral lung lobes, while in the remaining patients, lobular consolidation was predominantly localized in the unilateral upper or lower lung lobe since lower lobes were more commonly involved in patients with mechanical ventilation. No pure GGO were found all patients, in contrast, GGO combined with consolidation which was mostly unilateral or bilateral, was a single lobe distribution or random distribution was prone to be observed in patients with mechanical ventilation.

Nodules/masses were seen in merely 2 patients with mechanical ventilation, and bronchiectasis was found in only 1 patient. No significant interstitial abnormality (interlobular septal thickening or Honeycombing sign or crazy-paving sign) was found. Unilateral Pleural effusion was only found in two-thirds patients with mechanical ventilation. In addition, pericardial effusion was presented in 4 patients with mechanical ventilation.

CT findings between patients with mycoplasma infection and those without mycoplasma infection were similar (Fig.2). Focal consolidation with GGO were the main findings in the patients without mechanical ventilation. In contrast, for the patients requiring mechanical ventilation, predominant bilateral or unilateral lobular consolidation with GGO were indicated in 8 patients’ initial CT scans (Fig.3). Five patients showed focal consolidation in initial CT scans, then the temporal CT showed rapid progression including, more extensive unilateral or bilateral consolidation with adjacent GGO, and unilateral or bilateral pleural effusion (Fig.4).

Discussion
Human adenoviruses (HAdVs) are non-enveloped, double-stranded DNA viruses and common pathogens in children and cause a variety of diseases. Community-acquired adenoviral pneumonia is prone to occur in immunocompromised hosts and, the condition may also be a complication in immunocompetent patients[^6^]. There were no immunocompromised cases in the current study, the most common symptoms and signs were fever, myalgia and dry cough, which was consistent with previous reports[^4, 7^]. Most patients had the high fever. The patients also indicated some other
symptoms as other studies reported \(^8\), including dyspnea, diarrhea, pharyngeal congestion and sore throat. Tristan et al revealed that significant co-morbidity was uncommon among adenovirus pneumonia patients \(^8\). There were 10 patients in the present study showed combined mycoplasma infection which was similar with a previous study as it reported that co-infection of mycoplasma pneumonia was common in patients with adenovirus pneumonia\(^9\). Bacterial co-infections were identified in 28.5% (47/165) of adenovirus pneumonia patients \(^1\), in contrast, it was found in 10% cases in current study. However, there is no accurate association between co-infection and the adenovirus respiratory infections. Previous studies of pediatric patients showed that a peak positive rate of adenovirus infections occurred during March-April or spring \(^10, 11\). Yao et al\(^12\) reported Human adenovirus among hospitalized children was detected in every month throughout the study period from April 2017 to March 2018, peaking in August 2017. In current study, summer and winter were peak season of immunocompetent adult adenovirus pneumonia, which was partially similar with another study that reported seasonal peak for adenovirus infections in winter and spring in immunocompetent patients \(^13\).

Consistent with previous studies, the baseline laboratory findings including a normal total white cell count, decreased lymphocyte and increased C reaction protein \(^9, 14\) which suggest virus infection. Meanwhile, the elevated procalcitonin and neutrophil percentage may relate with coexisting mycoplasma or staphylococcus epidermidis. Furthermore, we also found that there were elevated LDH and CK levels in patients with adenovirus pneumonia which was similar to a study on an adenovirus-associated outbreak in a Military Training Facility \(^4\). Another important finding, patients with mechanical ventilation had a higher neutrophil percentage than patients without mechanical ventilation, suggesting patients suffering from co-infection may require more respiratory support.

In the current 20-patient series, the most frequent finding on CT is consolidation in all cases, whereas most observed was focal or lobar consolidation with lobular or peribronchovascular distribution. Patchy pure GGO were not common, but consolidation with surrounding GGO is the other common CT
finding. In immunocompetent military trainees\cite{1, 15}, consolidation was more commonly found than GGO in adenovirus pneumonia patients and the study of community-acquired adenovirus pneumonia revealed that consolidation, GGOs and pleural effusions were the most common findings in severe cases\cite{16} [17]. A research of Adenovirus pneumonia of 5 immunocompromised patients showed the extensive ground-glass opacities with or without consolidation were the main findings on HRCT\cite{18}. In contrast, hyperinflation and lobar atelectasis were reported commonly in infants and children\cite{19}. These suggests that consolidation with /without GGO in the early stage may be a key clue to suspecting adenovirus pneumonia for immunocompetent patients, although it resembles bacterial pneumonia. A case report and review of the literature reported bilateral interstitial infiltrates were the most common CXR in adenovirus pneumonia of immunocompetent adults\cite{8}. However, diffuse interstitial abnormalities were not found in the present study, which probably because it was masked by consolidation that appeared early\cite{20}.

Gu et al\cite{21} suggested that adenovirus pneumonia of patients with acute respiratory distress syndrome (ARDS) usually present rapid development of bilateral, mutilobar consolidation and patchy GGO which was more severe than patients without ARDS. In the current study, focal or subsegmental consolidation was more frequent in patients without mechanical ventilation, while patients with mechanical ventilation commonly indicated initial predominant lung consolidation or progress rapidly from initial focal consolidation to lobar consolidation, suggesting that patients required mechanical ventilation may be more prone to indicate intra-pulmonary abnormalities in CT scans. Consistent with previous studies\cite{13, 21}, 60% of this group of cases demonstrated pleural effusion and 20% of patients indicated pericardial effusion, which may be related to more serious abnormalities. That all Adenovirus pneumonia were confirmed with a positive finding of Adenovirus in bronchoalveolar lavage fluid is the strength of our research, however, our study has several limitations. The number of cases is small, which may partly be explained by the low incidence of adenovirus pneumonia in immunocompetent adults, however, we could miss more cases who didn’t
have bronchoalveolar lavage or mild cases. Because it is retrospective study, the scanning intervals of CT for patients were different leading to the dynamic changes on CT was unclear and adenovirus typing were not available leading to the relation of the clinical and CT findings with adenovirus typing remains unknown.

Conclusion
In conclusion, adenovirus pneumonia in immunocompetent patients manifested usually as significant consolidation with or without ground-glass opacities on CT. These findings are not specific for adenovirus pneumonia, but in adult patients with high fever, normal WBC count and decreased lymphocyte, consolidation with/without GGO on CT in the early stage may be a clue for suspecting adenovirus pneumonia.

Abbreviations
CT: Computed tomography
WBC: White blood cell
GGO: Ground glass opacity
BALF: Bronchoalveolar lavage fluid
IQR: Interquartile range
PCT: Procalcitonin
LDH: Lactate dehydrogenase
CK: Creatine kinase
ARDS: Respiratory distress syndrome

| Focal                       | 10 (50%)     | 4 (31%)        | 6 (86%)      |
| Multifocal                  | 10 (50%)     | 9 (69%)        | 1 (14%)      |
| Plueral effusion            | 12 (60%)     | 11 (85%)       | 1 (14%)      |
| Bilateral                   | 4 (20%)      | 3 (23%)        | 1 (14%)      |
| Unilateral                  | 8 (40%)      | 8 (62%)        | 0            |
| Pericardial effusion        | 4 (20%)      | 4 (100%)       | 0            |

Abbreviations: CT computed tomography; GGO, ground-glass opacity. Group 1, patients with mechanical ventilation; Group 2, patients without mechanical ventilation.

**Figures**
Figure 1

Onset time of the 20 patients with adenovirus pneumonia.

Figure 2

(A) A 48-year-old man with adenovirus pneumonia without mycoplasma infection, multifocal bilateral consolidation (arrows) was found in the picture; (B) A 46-year-old man with adenovirus pneumonia combined with mycoplasma infection, focal consolidation (arrow) with surrounding GGO (circle) was shown in the left lower lobe.
CT scans of the 2 cases with adenovirus pneumonia but without mycoplasma infection, and mechanical ventilation was performed in the patients. (A) Initial CT scan of a 39-year-old man showed predominant consolidation (arrows) with adjacent GGO (circle) in the bilateral lung lobes; (B) Initial CT scans of an 18-year-old man indicated multifocal consolidation in the bilateral lung lobes (arrows).

CT scans of a 41-year-old man with adenovirus pneumonia combined with mycoplasma infection, and mechanical ventilation was performed in the patient. (A) Initial CT scan showed focal consolidation (arrows) with adjacent GGO (circles) in the left lower lobe; (B) Rapid progression of consolidation in both lung zones (arrows) with surrounding GGO (circles) after 5 days; (C) Left pleural effusion was also observed.
