Abstract
In this paper, a dual-core microchannel-based fiber sensor is studied by using finite element method in the visible and near-infrared bands. Plasmonic material gold (Au) is deposited in microchannel to generate the surface plasmon resonance (SPR) effect, so that sensor can detect the change in RI of its surrounding analyte. Simulation results show that the maximum wavelength sensitivity and resolution are 33600 nm/RIU and $2.97 \times 10^{-6}$RIU for y polarization in the RI range of 1.33 to 1.44, respectively. The highest figure of merit (FOM) of the sensor is 961 for y polarization. In addition, we study the effects brought by the structural changes of the fiber sensor, and the results show that the design of “microchannel coating” dramatically improves the refractive index (RI) detection ability of the sensor. The D-shaped dual-core microchannel-based photonic crystal fiber sensor proposed in this paper has a simple structure, low manufacturing complexity, and high sensitivity. Combined with external sensing technology, this sensor has great application potential in the fields of biotechnology, medical diagnosis, and environmental protection.

Keywords Surface plasmon resonance · Wavelength sensitivity · Microchannel · Dual-core

Introduction
Photonic crystal fiber based on surface plasmon resonance (SPR) is widely applied in biotechnology, medical diagnosis, and environmental protection due to its high sensitivity to variation of RI [1]. SPR is an optical phenomenon. Evanescent wave will be generated when electromagnetic wave has a total internal reflection on the surface of the dielectric and evanescent wave can stimulate the surface electron oscillation of metal, and then surface plasmons (SPs) are generated. When the frequency and wavenumber of the SPs and evanescent wave are equal, the two will resonate, and a part of the electromagnetic wave is absorbed; The continuous resonating generates surface plasmon wave (SPW), which are very sensitive to variation of RI [2]. The variation of RI of the analyte adjacent to the metal film will affect the propagation constant of the related modes, the resonance peak of the core mode will shift.

Conventional prism-based SPR coupling configurations were Otto [3] and Kretschmann and Heinz [4]. These prism-based SPR coupling configurations are composed of various mechanical and optical elements and suffer from disadvantages of bulkiness, unreliable mechanical structure, high cost, and unsuitable for distributed sensing and mass production [5]. The PCF-based SPR sensor has the advantages of miniaturization, flexible design, lightweight, easy integration and real-time monitoring, and is suitable for medical diagnostics and environmental monitoring [6]. Compared with traditional optical fiber, PCF has many superiorities, such as multi-dimensional structure, large mode area, wide coordination range and multi-parameter measurement [7].

The sensor’s performance depends mainly on the plasmonic materials and gold, copper, silver, aluminum, etc., are ubiquitous plasmonic materials [8, 9]. Silver offers a high resonance peak [10], but suffers from an oxidation issue in an aqueous environment, which means that gold without...
oxidation issue has better chemical stability and is more suitable for microfluidic analytes than silver. The defect of oxidation can be solved by employing a layer of graphene or indium tin oxide (ITO) or titanium dioxide in nanoscale. This increases not only the fabrication complexity but also manufacturing cost [11].

Recent researches of SPR sensors based on PCF generally comprise two types: internal sensing approach and external sensing approach [12]. The former requires filling the analyte into a specific air hole in the fiber. However, it is not feasible for the real-time sensing application due to the difficulty of filling or emptying the analyte. These disadvantages can be overcome by external sensing technique. Currently, this technique has become popular due to its simple detection [13]. For example, in 2019, H. Thenmozhi et al. proposed an ITO-based D-shaped PCF-SPR sensor showing maximum wavelength sensitivity and resolution of 50000 nm/RIU and 4 × 10⁻⁶ RIU [14]. In 2019, Md. Nazmus Sakib et al. described a dual-core D-shaped PCF sensor that uses gold as plasmonic material and shows maximum wavelength sensitivity and resolution of 80000 nm/RIU and 1.25 × 10⁻⁶ RIU [15]. In 2019, Shivam Singh et al. developed a D-shaped PCF sensor with gold and graphene layers. The maximum sensitivity obtained is 33500 nm/RIU in the sensing RI range of 1.32 to 1.40 [16]. In 2020, Q.M. Kamrunnahar et al. proposed a simple circular lattice dual-core PCF-based plasmonic sensor [17]. This sensor provides the maximum wavelength sensitivity and resolution of 11200 nm/RIU and 8.92 × 10⁻⁶ RIU for wavelength sensing within the RI range of 1.33 to 1.44. In 2020, Hasan Sarker et al. studied a “slotted PCF based plasmonic biosensor”, maximum wavelength sensitivity and wavelength resolution are 22000 nm/RIU and 4.54 × 10⁻⁶ RIU [18]. In 2020, Md. Biplob Hossain et al. proposed a D-shaped PCF sensor based on SPR [19]. The proposed sensor shows the highest sensitivity of 15,000 nm/RIU and the maximum resolution is 6.67 × 10⁻⁶ RIU in the RI detection range of 1.42 to 1.46. In 2021, Shivam Singh et al. proposed a dual side-polished PCF RI sensor [1]. Gold, TiO₂, Si₃N₄ are coated on a polished plane fiber surface. The maximum wavelength sensitivity and RI resolution reach 35000 nm/RIU and 4.347 × 10⁻⁶ RIU, respectively. The above sensors have obtained high wavelength sensitivity but still exist some problems such as narrow detection range, high preparation complexity, and high cost.

In this paper, the SPR-based dual-core sensor with microchannel has been proposed and numerically analyzed by the finite element method (FEM). The plasmonic metal gold is deposited on the surface of the microchannel to enhance the sensor’s performance. Numerical results show maximum wavelength sensitivity and resolution of 33600 nm/RIU and 2.97 × 10⁻⁶ RIU, respectively. Within the RI range of 1.33 to 1.44, obtained FOM of the sensor is 961 RIU⁻¹. The proposed sensor not only has high wavelength sensitivity but also low preparation complexity. In addition, due to the advantages of external sensing, the process of filling and cleaning the analyte is removed. The detection efficiency is greatly enhanced.

Structure Design and Modeling

In Fig. 1, the cross-section of the proposed PCF sensor can be seen. The designed architecture of the PCF is consisted of air holes arranged in rhombus lattice. The distances of each air hole to its adjacent air hole in the y direction and x direction are λ and 2λ, respectively. The diameter of small air holes and big air holes is denoted by d₁ and d₂, respectively. The optimized parameters are λ = 2 μm, d₁ = 0.95 μm, d₂ = 1.65 μm. The three microchannels are located above the fiber core to boost up the coupling between core mode and SPP mode. In order to better realize surface plasmon resonance, gold is used as a plasmonic material to coat the microchannel. The thinner the gold film, the fewer free electrons. The thicker the gold film, the less energy transmission from core to gold film [20]. Taking into account the above constraints and existing technology, the thickness of the gold film (t_g) was set to 40 nm. The vertical height (h) of the microchannel center and the fiber core is 3 μm. To absorb the radiated energy, a perfectly matched layer (PML) of 2 μm thickness has been set around the fiber.

The proposed sensor uses fused silica as background material, and the refractive index of fused silica is given by Sellmeier equation [21]:

\[
n_{SiO_2}^2(\lambda) = 1 + \frac{A_1 \lambda^2}{\lambda^2 - B_1} + \frac{A_2 \lambda^2}{\lambda^2 - B_2} + \frac{A_3 \lambda^2}{\lambda^2 - B_3}
\]

where \(\lambda\) is the wavelength of the incident light, \(A_1 = 0.696166300, A_2 = 0.407942600, A_3 = 0.897479400, B_1 = 4.67914826 \times 10^{-3} \mu m^2, B_2 = 1.35120631 \times 10^{-2} \mu m^2, B_3 = 97.9340025 \mu m^2\). The dielectric constant of gold is given by Drude model [22]:

\[
\varepsilon_{Au}(\omega) = \varepsilon_{\infty} - \frac{\omega_p^2}{\omega(\omega + i\omega_s)}
\]

where \(\varepsilon_{\infty} = 9.75, \omega_p = 1.36 \times 10^{16} \text{rad/s}, \omega_s = 1.45 \times 10^{14} \text{rad/s}\).

Results Analysis and Discussion

The parameters of fiber sensor mainly include confinement loss, wavelength sensitivity, resolution, and so on. The sensor proposed in this paper will be studied in the above parameters. The confinement loss is determined by the
structure of photonic crystal fiber, such as the number, size, and arrangement of air holes, and also depends on the wavelength of the incident electromagnetic wave. Confinement loss is defined by following equation [23, 24]:

$$a_{\text{loss}}(dB/m) = 40\pi \frac{\text{Im}[n_{eff}]}{\ln(10)\lambda}.$$  

(3)

where $\lambda$ is wavelength in meter, $\text{Im}[n_{eff}]$ is the imaginary part of the effective mode RI. Figure 2 displays variation in the loss when the RI of analyte changes from 1.33 to 1.44. The maximum loss is obtained at resonant wavelengths of 562 nm, 572 nm, 584 nm, 598 nm, 614 nm, 633 nm, 655 nm, 681 nm, 721 nm, 760 nm, 1077 nm, 1413 nm. As we can see in Fig. 2, when the RI of analyte changes from 1.33 to 1.44, confinement loss increases from 288 dB/m to 3307 dB/m with red-shift of resonance peak. The analytes with higher RIs have greater capability to influence the SPP mode effective refractive index. The phase-matching point of the core mode and SPP mode is red-shifted with the increase of RI; Under the condition of constant RI, the effects of different wavelengths on the gold film are different. As the RI of the analyte increases, it is closer to the RI of the fiber core, which will lead to a strong coupling of the core mode and SPP mode with a corresponding increase in confinement loss.

Figure 3a depicts the dispersion relationship for the loss curve, y-polarized core mode and SPP mode for an analyte RI 1.42. We mainly analyze y polarization because of the stronger interaction between y polarization and gold film. The red line represents the variation curve of the confinement loss for y-polarized core mode, while...
the purple and green line show the effective RI of SPP mode and the real part of the effective RI of core mode, respectively. In Fig. 3a, purple line and green line intersect at resonant wavelength of 760 nm for the analyte RI of 1.42, which means that the phase matching condition is fulfilled, the coupling between the SPP mode and core mode is achieved, and maximum energy is transferred from the core mode to the SPP mode. The effective RI of SPP mode decreases faster than that of core mode, the coupling intensity of the two modes decreases, and the loss decreases gradually when the two modes are far from the intersection. Figure 3b-d displays field distribution of SPP mode, y-polarized and x-polarized core-guided mode for the analyte RI of 1.42.

Wavelength sensitivity (WS) is an important parameter to describe the performance of PCF sensor, which represents the shift of the sensor to the resonance peaks of different RI analytes. Wavelength sensitivity is defined by using wavelength interrogation method [25]:

$$S_{\lambda}(\text{nm/RIU}) = \frac{\Delta \lambda_{\text{peak}}}{\Delta n_{a}}$$

Figure 4 depicts the variation curves of wavelength sensitivity and resonance wavelength. The black line in Fig. 4 shows that the resonance wavelength increases with the increase of RI. However, this paper argues that the resonance wavelength will not increase infinitely. In this case [17], the characteristics of the loss curves...
gradually change with increasing RI. The curves decreases more and more slowly as RI increases. From its variation law, it can be judged that when the RI is greater than 1.44, the loss curve may not have a peak or may have a peak but the FWHM (full width at half maximum) is very large. For these reasons, data with a RI greater than 1.44 are discarded. This limits the increase in resonance wavelength. The shift of resonance wavelength is 10 nm, 12 nm, 14 nm, 16 nm, 19 nm, 22 nm, 26 nm, 40 nm, 39 nm, 317 nm, 336 nm at analyte RI of 1.34 to 1.44; The red line shows the variation of WS, and WSs obtained at RIs of 1.42 and 1.43 is 31700 nm/RIU and 33600 nm/RIU, respectively.

Sensor resolution is a parameter that is used to measure the lowest change of analyte RI that can be detected by the sensor. The sensor resolution can be defined as [26]:

$$R(\text{RIU}) = \frac{\Delta n_a \times \Delta \lambda_{\text{min}}}{\Delta \lambda_{\text{peak}}}$$  \(\text{(5)}\)

where $\Delta n_a$ is the variation of the analyte RI, $\Delta \lambda_{\text{min}}$ is the minimum spectral resolution, and $\Delta \lambda_{\text{peak}}$ is the shift of resonance wavelength. The maximum resolution of proposed sensor is $2.97 \times 10^{-6}\text{RIU}$ with $\Delta n_a=0.01$ nm, $\Delta \lambda_{\text{min}}=0.1$ nm and $\Delta \lambda_{\text{peak}}=336$ nm. The value suggests the sensor can detect the analyte RI with a change in the order of $10^{-6}$ for analyte RI of 1.43.

Preserving the polarization state is important in sensing and long-distance communication. The ease of birefringence is due to the flexible structural design and optical properties of PCF. There are two types of core modes: x- and y-polarized core modes. The real part of the effective RI of the x-polarized core mode is different from that of the y-polarized core mode. Birefringence ($B$) is defined as the difference in the RI real parts for the two orthogonal polarizations [27]:

$$B = |\text{Re}(n_{eff}^x) - \text{Re}(n_{eff}^y)|$$  \(\text{(6)}\)

Figure 5 reveals variation curves of birefringence, the RI real parts of x and y polarizations for analyte RI of 1.44. The birefringence increases gradually and the real part of the effective RI of both polarizations decreases gradually with the increase of wavelength. Birefringence of $1.6 \times 10^{-3}$ can be obtained at 1523 nm wavelength for analyte RI of 1.44.

In addition, the figure of merit (FOM) can be calculated as the ratio of WS to full width at half maximum (FWHM) to evaluate the overall performance of a sensor [28–30]. When the WS increases, the FWHM should be as small as possible, so that when the RI of analyte changes, we can observe the red shift or blue shift of the loss peak clearly. Table 1 shows the obtained FOM for different analyte RI.

### Analysis and Discussion of Structure Parameters

The changes in the structure of the sensor will affect the parameters (confinement loss and resonance wavelength) of the sensor. This chapter will discuss the influence brought by the change of structural parameters, including the size of the air hole, the position of the gold coating, and the vertical distance $h$ between the polished plane and the fiber core.

Figure 6 shows the influence on the loss when the diameter of the air hole D changes from 0.95 μm to 2.1 μm. It can be observed that the loss peak value gets higher with increasing diameter value. When the diameter of air hole D is large, the energy of the two cores has little influence on each other, and the energy in the core produce a stronger SPR effect with the gold film, resulting in a larger loss peak. Compared with the case of larger air hole D diameter, the case of smaller D diameter leads to larger dual-core, which means that the dual-core has a stronger ability to limit
energy. In this case, the smaller the SPR effect, the smaller the loss. When the diameter of the air hole D is constant, the phase-matching point of the core mode and SPP mode is red-shifted with the increase of RI, which results in the resonance peak red-shifted. As the RI of the analyte increases, it is closer to the RI of the fiber core and will cause the strong coupling of the core mode and SPP mode, the loss value increases correspondingly.

The coating position of the gold film also affects the performance of sensor directly. Figure 7a reveals the loss curves of sensors with different coating positions (inner wall of microchannel, polished plane). Figure 7b depicts SPP mode for the sensor with microchannel coating. Position1 and Position2 are used to represent the microchannel coating and polished plane coating, respectively. It can be seen from the Fig. 7a that when the analyte RI changes from 1.38 to 1.41, the loss curves of the two coating methods both show that the resonance peak red-shifts with the increase of wavelength. For the same analyte RI, the difference between the two coating methods is that the loss of polished plane coating is smaller than that of microchannel coating. This is because the polished plane coating method increases the distance between the gold film and the fiber core and weakens the resonance intensity between the incident electromagnetic wave and metallic electrons. With an increment of analyte RI, the loss peak value of polished plane coating increases faster than that of microchannel coating, which is related to broader passage along the y-axis direction. Figure 8 displays the loss curves of the sensor with microchannel coating (Position1), both microchannel and polished plane coating (Position 3). Combining with Fig. 7, it can be inferred that microchannel coating and polished plane coating exhibit a larger resonance shift than that of both microchannel and polished plane coating, indicating that the two coating methods of microchannel coating and polished plane coating improve the sensor’s performance. In addition, our data show that the microchannel coating method has better detection ability than the polished plane coating method when the analyte RI > 1.41. Considering the characteristics of the loss curve of the sensor with polished

| RI   | 1.33 | 1.34 | 1.35 | 1.36 | 1.37 | 1.38 | 1.39 | 1.40 | 1.41 | 1.42 | 1.43 | 1.44 |
|------|------|------|------|------|------|------|------|------|------|------|------|------|
| FOM  | 40   | 50   | 54   | 64   | 68   | 73   | 87   | 98   | 111  | 961  | 210  | N/A  |

Fig. 6 Loss peak variation with air hole diameter for the analyte RI from 1.38 to 1.40

Fig. 7 (a) Variation in loss peaks for sensors with microchannel coating and polished plane coating. (b) SPP mode of the sensor with polished plane coating
plane coating, it is suitable for the sensing range of low RI, and it’s possible to apply the sensor to different application cases by coating plasmonic material in different positions. For example, biodiesel has a RI of 1.437 at a wavelength of 1.4 μm and a temperature of 20°C [31]. The sensor with microchannel coating can be used to detect the water content of biodiesel. The RI of silicone oil is 1.4094 (20°C) [32]. The sensor with polished plane coating can be used to detect the purity of silicone oil.

From Fig. 9 we can see that the vertical distance \( h \) between the polished plane and the fiber center has significant impact on the sensor property. It can be observed that when the distance \( h \) increases from 3.0 μm to 3.4 μm, the loss peak value decreases. This indicates that the further distance between the center and the gold film, the less energy transferred from the core to the gold film, which means that the coupling intensity between the SPP mode and the core-guided mode gradually decreases, and the loss decreases accordingly. In addition, the changed phase matching point of core-guided mode and SPP mode with the increase of the analyte RI resulting in a red-shifted resonance peak. The stronger coupling degree of the core-guided mode and the SPP mode is related to the fact that the RI of the analyte is closer to the effective RI of the fiber core, and the loss peak value increases gradually.

**Conclusion**

An SPR-based microchannel dual-core PCF sensor is proposed and analyzed numerically with an analyte detection range of 1.33 to 1.44. Simulation and analysis depict that the maximum wavelength sensitivity, resolution was obtained as 33600 nm/RIU and 2.97 × 10^{-6}RIU, respectively, for the sensing range of 1.33 to 1.44. Furthermore, the sensor can achieve a birefringence of 1.6 × 10^{-3} and a maximum FOM of 961RIU^{-1} for the y polarization. Moreover, not only the performance of the sensor was improved, but also the convenient detection method is realized because of the micro-channel coating and dual-core structure. The sensor can be directly immersed in the microfluidic analyte for detection, which solves the problem of analyte filling and cleaning. The sensor proposed in this paper has good performance which has potential applications in biotechnology and chemical sensing fields.
