Increasing dimethyl ether production from biomass-derived syngas via sorption enhanced dimethyl ether synthesis

Dalia Liuzzi, Cristina Peinado, Miguel A. Peña, Jasper van Kampen, Jurriaan Boon and Sergio Rojas

The direct synthesis of dimethyl ether (DME) from biomass-derived syngas is a topic of great interest in the field of biofuels. The process takes place in one reactor combining two catalytic functions, Cu/ZnO/Al2O3 (CZA) for the synthesis of methanol and an acid catalyst (typically γ-Al2O3) for methanol dehydration to DME. However, the catalytic performance of those catalysts is negatively affected by the high CO2/CO ratio in the bio-syngas, resulting in low methanol and DME production rates. In this work, we show that promoters such as zirconium and gallium oxides increase the CO fraction in the syngas. However, the production of H2O is also increased, leading to the deactivation of both CZA and γ-Al2O3. The addition of a water sorbent (zeolite 3A) in the reaction medium alleviates the detrimental effect of H2O in the direct synthesis of DME from CO2-rich syngas. Thus, DME production over the CZA/γ-Al2O3 catalytic bed increases from ca. 8.7% to 70% when a zeolite 3A is placed in the reaction medium. In fact, carbon conversions higher than conventional equilibrium conversions are achieved. This work demonstrates that the sorption enhanced synthesis of DME is a suitable strategy to increase DME production from biomass-derived syngas.

Introduction

The use of biomass or municipal solid waste as feedstock to produce transportation fuels and chemicals is a central policy to address environmental and oil dependence issues of today's society. The range of products that can be obtained through the different routes for biomass transformation covers from hydrogen and light hydrocarbons, to liquids fuels including diesel and kerosene.1,2 Among those, dimethyl ether (DME) stands out as an excellent diesel substitute for ignition engines providing very low NOx and soot in the exhaust gases.3,4 DME production from biomass gasification is a multistep process which includes biomass gasification, syngas conditioning, production of methanol and methanol dehydration to DME among its chemical unit operations.5,6 Usually, the syngas obtained from biomass shows a CO2/CO ratio significantly higher than the optimum one for the synthesis of methanol, around 3–5% CO2,6 resulting in low once through carbon conversion.7–9 Methanol synthesis from syngas and dehydration steps can be carried out in separate reactors, or within a single reactor.

Recently, the direct synthesis of DME from (biomass-derived) syngas or from pure CO2 is attracting a great deal of attention.4,10,11–15 During the direct synthesis of DME, the following reactions take place simultaneously; CO and CO2 hydrogenation to methanol (eqn (1) and (2)), water gas shift reaction (WGS) {eqn (3)}, and the dehydration of methanol to DME {eqn (4)}.

\[
\begin{align*}
\text{CO} + 2\text{H}_2 & \rightarrow \text{CH}_3\text{OH} \\
\text{CO}_2 + 3\text{H}_2 & \rightarrow \text{CH}_3\text{OH} + \text{H}_2\text{O} \\
\text{CO} + \text{H}_2\text{O} & \rightarrow \text{CO}_2 + \text{H}_2 \\
2\text{CH}_3\text{OH} & \rightarrow \text{CH}_3\text{OCH}_3 + \text{H}_2\text{O}
\end{align*}
\]

The direct synthesis of DME intends to mitigate the strong thermodynamic limitations of syngas conversion to methanol by shifting the equilibrium as methanol produced is dehydrated and thus removed from the system.4 The direct synthesis of DME entails the use of two different catalytic phases, one for the synthesis of methanol from syngas and one for DME production. Cu–ZnO–Al2O3 (CZA) materials are the benchmark catalysts for the synthesis of methanol from syngas,1,12,16,17 whereas acidic solids such as γ-Al2O3,18 zeolites,19,20 acidic oxides21 or heteropolyacids22–25 are the most active catalysts for the methanol dehydration to DME.

Cu5, or more likely the Cu/ZnO interphase is considered as the active site for the methanol production.26,27 The dependence...
of the activity on the morphology and size of copper particles and the effect of promoters such as Mn, Zn, Zr, Cu or Ga, have been discussed thoroughly in the literature. The main carbon source for methanol, either CO or CO₂, is also a recurring topic in the literature. Although there is seemingly an agreement in that methanol is mostly produced from CO₂ (eqn (1)), other authors claim that the relative hydrogenation rate of CO and CO₂ depends on the conditions and the CO₂/CO ratio of the syngas. In part, the lack of consensus arises from the interconversion between CO and CO₂ during methanol (and direct DME) synthesis through the WGS reaction (eqn (3)). Regardless of the actual source of methanol, it is well admitted that methanol production rates from CO₂ rich syngas are slower than from CO rich ones. On the one hand, the presence of a small amount of CO₂ in the syngas is beneficial for the synthesis of methanol because it promotes the partial oxidation of metallic Cu into Cu⁺, which increases methanol production rates. On the other hand, CO₂ has an inhibitory effect since it adsorbs strongly on the active sites thus poisoning the catalyst. In addition, the presence of CO₂ in the syngas results in the production of H₂O in the reaction medium via the reverse water gas shift and methanol synthesis reactions (eqn (2) and (3), respectively). Water is a major source of catalyst deactivation, causing the agglomeration of the Cu particles in CZA and the deactivation of γ-Al₂O₃. Moreover, since H₂O is produced along with methanol and DME, a high partial pressures of H₂O in the reaction medium also inhibits methanol and DME production. Martin et al. reported that the optimum CO₂ content for the methanol synthesis is 2.4 vol%. Sadly, the CO₂ content of biomass-derived syngas is usually well above this optimum value. From the catalytic point of view, it has been reported that the use of promoters such as Zr or Ga oxides increase conversion rates of rich CO₂ syngas mixtures over CZA. However, this strategy also results in a high production of H₂O, which has to be eliminated from the reaction medium. The use of water permselective membranes or high capacity of water adsorption materials are the main technologies proposed for the in situ removal of water from carbon hydrogenation reactions. Recent studies about the effect of in situ water removal during the synthesis of DME by placing sorbent materials in the reactor have been published. This strategy, which is coined as sorption enhanced DME synthesis (SEDMES), aims to intensify the production of DME from syngas by shifting the equilibria towards the production of methanol and DME via H₂O removal. Whilst a relatively large body of work on the direct synthesis of DME is available and although some theoretical models on SEDMES and its cycling design have been published, very few experimental studies on this process have been reported hitherto. Moreover, studies conducted with CO₂-rich syngas such as that obtained from biomass gasification, which results in higher production of H₂O, are lacking in the literature.

In this work, we study the synthesis of methanol (MeS), the direct synthesis of DME (DDMES) and the sorption enhanced DME synthesis (SEDMES) using CO₂-rich syngas (CO₂/CO molar ratio of 1.9; a composition similar to that obtained from biomass-derived syngas) using CZA and γ-Al₂O₃ catalytic mixtures. With the aim to adjust the CO₂/CO syngas ratio within the reaction medium, we doped CZA with ZrO₂ and Ga₂O₃ that are known to promote the r-WGS reaction. SEDMES experiments were conducted by using zeolite 3A as H₂O adsorbent in the catalytic bed. A remarkable increase of DME production and carbon conversion was observed in the SEDMES experiments.

### Experimental

#### Synthesis of catalysts

Copper–zinc oxide–alumina (~zirconia–gallium oxide) catalysts used in this study were synthesized by the coprecipitation technique at controlled pH and temperature. An aqueous solution of the metal nitrates (Cu(NO₃)₂·3H₂O; Zn(NO₃)₂·6H₂O; Al(NO₃)₃·9H₂O; Zr(NO₃)₄·xH₂O and Ga(NO₃)₃·xH₂O) in the desired proportion, but maintaining a total concentration of 2 M was prepared. The solution containing the nitrate precursors and a 1.6 M solution of Na₂CO₃ were added simultaneously and dropwise to a flask containing 100 mL of Milli-Q water at 70 °C. The rate of addition was controlled to maintain a pH value of 7 for the zirconia-containing catalysts and 8 for the catalyst without zirconia, under continuous stirring. Once the addition was completed, the mixture was aged for 12 hours at room temperature. The solid obtained was recovered by filtration and rinsed with Milli-Q H₂O until the pH of the recovered liquid is ca. 7. The solid obtained was dried at 70 °C during 12 h, crushed and calcined under static air at 325 °C during 2.5 h. The Cu content in all catalysts is ca. 60% (see Table 1). The catalysts with ZrO₂ are labelled as CZAZ, and the Ga₂O₃ containing catalysts are referred to as CZAZGa. The actual Cu, ZnO, ZrO₂ and Ga₂O₃ contents in the catalysts are shown in Table 1. A commercial catalyst for methanol synthesis (CZA_comm) was used as benchmark. The zeolite sample Molsieve Type 3A (MS-1014, lot 289000651) was purchased from UOP/ASGE (New York, USA).

| Catalyst | Surface area, m² g⁻¹ | Pore diameter, nm | Composition (wt%) | d(Cu) nm | S(Cu) (XRD), m² g⁻¹ | D(Cu) % | S(Cu) (chem N₂O₃), m² g⁻¹ |
|----------|----------------------|-------------------|--------------------|----------|---------------------|--------|--------------------------|

Zeolite 3A lacks of acidity. γ-Al2O3 (acidic catalyst) was purchased as 3 mm pellets (assay >98%, Riogen NJ, USA).

Characterization
Specific surface areas and pore size distribution were determined from the N2 adsorption–desorption isotherms collected in an Asap2020 Micromeritics at −196 °C after degasification at 140 °C.

X-ray diffractograms were obtained in a polycrystal X-ray X’Pert Pro PANalytical with a configuration θ–2θ, using CuKα radiation (wavelength of 0.15418 nm), and an Anton Paar XRK900 was used for the pre-treatment of the samples under reductive atmosphere. The size of the Cu crystallites ($d_{Cu}$) was calculated with the Scherrer equation (eqn (5)).

$$d_{Cu} = \frac{K\lambda}{\beta \cos \theta}$$  \hspace{1cm} (5)

where $K$ is the Scherrer constant, 0.94 for spherical crystals with cubic symmetry, and $\lambda$ represents the wavelength of the incident radiation. $\beta$ and $\theta$ are the full width at half maximum (FWHM) and the position of the diffraction peak, respectively. Based on the calculated $d_{Cu}$, the surface area of the reduced copper particles ($S_{Cu,m,Cu}$) was calculated with eqn (6), in which $\rho_{Cu}$ is the density of copper (8.92 g cm$^{-3}$) and Cu content is the mass fraction of copper in the catalyst.

$$S_{Cu}(XRD) = \frac{6000 \times \text{Cu content}}{\rho_{Cu} \times d_{Cu}}$$  \hspace{1cm} (6)

The chemical composition of the catalysts was analyzed in an inducted coupled plasma-optical emission spectroscopy PlasmaQuant PQ 9000 Analytik Jena, after proper digestion of the solid.

Cu dispersion and Cu surface area were determined from N2O chemisorption. First, a temperature-programmed reduction (TPR-t) was performed by subjecting the catalyst under study to a thermal treatment between 25 to 280 °C at a rate of 2 °C min$^{-1}$, under a gas flow of H2/N2 20/80 v/v. The temperature was decreased to 30 °C, and N2O was flown through the reactor at 30 °C during 15 min. Once the chemisorption ended, non-chemisorbed N2O was flushed under flowing He during 30 minutes. In this step, surface Cu species are selectively oxidized to Cu2O. Next, a second TPR (TPR-s) was performed from 30 to 280 °C, with a heating rate of 10 °C min$^{-1}$ under a H2/N2 20/80 flow. The hydrogen consumed in TPR-t stands for the totality of the copper in the catalyst. The hydrogen consumed in TPR-s accounts to the reduction of surface copper species (Cu2O) oxidized during the N2O chemisorption step. Cu dispersion ($D_{Cu}$) was calculated from eqn (7).

$$D_{Cu}(\%) = \frac{2 \times \text{area TPR-s}}{\text{area TPR-t}} \times 100$$  \hspace{1cm} (7)

The value of the surface area occupied by an atom of Cu in a polycrystalline surface, $a_{m,Cu}$, is 6.85 m$^2$ per atom of Cu. $N_A$ is the Avogadro number and $M_{Cu}$ is the atomic mass of Cu (63.55 g mol$^{-1}$). For the number of copper sites per gram of catalyst, eqn (9) was used.

$$\text{Cu sites}_{cat,i} = \frac{S_{Cu}(\text{chem N}_2O) \times \rho_{S,Cu}}{N_A}$$  \hspace{1cm} (9)

where Cu sites$_{cat,i}$ is the number of copper sites in catalysts i, in moles of copper per g, and $\rho_{S,Cu}$ is the surface density of copper, which is 1.47 × 10$^{19}$ atoms per m$^2$.

Catalytic tests

Synthesis of methanol (MeS) 
The catalytic tests were performed in a fixed-bed stainless-steel reactor with a diameter of 0.9 cm. The catalytic bed consisted of 200 mg of catalysts sieved at 250–300 μm fraction and diluted in SiC to avoid hot spots. The catalysts were pre-treated in situ in a H2/N2 20/80 vol current at 250 °C during 2.5 h. Afterwards, the reactor was cooled to 100 °C in N2 and then pressurized to 25 bar with a syngas, similar to biomass-derived syngas, with a CO/CO2/H2/N2 volumetric composition of 1/1.9/7.7/1.18 (Air Liquid), so that the M module ([[H2–CO2]/[CO + CO2]] = 2. Once reached this pressure, the reactor was heated to 270 °C and the proper flow of syngas to get a GHSV = 7500 h$^{-1}$. Reaction outlet gases were analysed with an on-line Varian CP-3800 gas chromatograph equipped with a Hayesep Q packed column connected to a thermal conductivity detector (TCD) and a Rtx-1 capillary column connected to a flame ionization detector (FID). N2 was used as internal patron for the calculations of CO and CO2 conversions. The methanol produced was calculated taking into account that it was the only product, since no other compound different to the ones in the feed was observed. The activity of each catalyst was measured for at least 5 hours. The composition of the outlet gases was analysed three times and the values reported in this work are the averaged values.

CO and CO2 conversions were calculated as indicated in eqn (10).

$$X_i = \frac{\text{mole flow}_{i,in} - \text{mole flow}_{i,out}}{\text{mole flow}_{i,in}}$$  \hspace{1cm} (10)

where $X_i$ represents the conversion of compound i (CO or CO2), and mole flow$_{i,in}$ and mole flow$_{i,out}$ are the inlet and outlet mole flows of compound i, respectively, in moles per s. For the turnover frequency numbers (TOF, in s$^{-1}$), eqn (11) and (12) and were used.

$$\text{TOF} = \text{methanol production (MeS)} / (\text{Cu sites} \cdot g_{\text{cat}})$$  \hspace{1cm} (12)

Methanol production in MeS is expressed in moles per s, and $g_{\text{cat}}$ represents the grams of catalyst loaded to the reactor. Since methanol is the only product detected, methanol production during the MeS was calculated form eqn (11).

Direct synthesis of DME (DDMES) and sorption enhanced DME synthesis (SEDMES). The metallic and acidic catalyst were
crushed to powder, mixed in a 1 : 1 weight ratio, pelletized, and finally crushed and sieved to 212–425 μm. The adsorbent zeolite 3A was also crushed and sieved to the same fraction. The catalytic bed was prepared mixing the catalysts and the zeolite in a ratio 1 : 4 (weight basis) and diluted with SiC in order to avoid the hot spots formed during the reaction.

The DDMES and SEDMES experiments were conducted on the high-pressure multi-column rig (‘Spider’), with 8 reactors of 20 mm internal diameter. 5.3 g of a 1 : 1 catalyst mixture of the Cu-based and acid catalyst plus 21 g of 3A zeolite was loaded in each reactor. A flow of 90 NmL min⁻¹ of simulated syngas (CO₂/CO = 2, and M = (H₂ – CO₂)/(CO + CO₂) = 2) was fed to each reactor at 275 °C, 25 bar. The catalytic mixture was activated under H₂/N₂ flow (20/80 v/v) at 250 °C and 1 bar during 2.5 h. Product analysis was performed by gas chromatography (GC, equipped with a TCD and a FID detector) and mass spectrometry, by monitoring the following species; hydrogen (m/z = 2), water (m/z = 18), carbon monoxide/nitrogen (m/z = 28), argon (m/z = 40), carbon dioxide (m/z = 44) and DME (m/z = 46).

Traces of C₂H₄ (m/z = 28) were detected, but due to the extremely low intensity of the signal, it was not considered. C₂H₄ comes from the further dehydration of DME in presence of an acid catalyst,⁵⁰,⁵¹ so the assumption that CO and CO₂ converted only form methanol is still valid for these experiments. All experiments were performed in triplicate. The first was always discarded, the second and third reached very similar results.

The data for the SEDMES regime were those collected during the early stages of the reaction, in the transient state (ca. 50 minutes), when the adsorbent zeolite was still dry. The data collected once the zeolite is saturated, at steady state, represent the DDMES (after ca. 100 minutes). The adsorption capacity of the zeolite is regenerates in situ. The regeneration protocol consisted in a periodic switching to dry nitrogen, followed by decreasing the pressure to 3 bar and increasing the temperature to 400 °C. For every setting, the reaction and the regeneration were measured for every sample.

### Results

#### Characterization

Table 1 displays the specific surface areas, pore diameters, elemental composition, and results of RXD and N₂O chemisorption of the catalysts studied in this work. As shown in Table 1, all catalysts have similar Cu loading of 60–67 wt%. CZA_comm displays the largest specific surface area in the series. Its homemade analogue (CZA) displays a lower surface area due to the lower content of Al₂O₃. The addition of ZrO₂ (CZAZ) increases the surface area of the material. On the other hand, the catalyst with gallium presents the lowest surface area of the series. The CZA_comm shows a narrow distribution of the pore sizes, while the rest of the catalysts present a bimodal distribution or a very wide range in the diameter of their pores, which are larger than in the commercial catalyst.

The X-ray diffractograms for the catalysts reduced in H₂/N₂ at 250 °C (heating rate 2 °C min⁻¹) are shown in Fig. 1. All diffractograms display the characteristic diffraction lines for metallic Cu, with peaks at 43, 50, 74° and ZnO at 32, 35, 37 and 57°. The absence of diffraction peaks for Al₂O₃, ZrO₂ or Ga₂O₃ indicates that these phases are amorphous highly dispersed on the solid.

Table 1 reports Cu dispersion and surface areas of the catalysts as determined from N₂O chemisorption. Sadly, it was not possible to conduct N₂O chemisorption experiment with the Ga-doped sample, CZAZGa, because Ga₂O₃ reduction overlaps with the reduction of Cu,³² invalidating the assumption that hydrogen consumption during the experiment accounts only to the reduction of copper. Therefore, we also calculated Cu dispersion and surface area of all catalyst from the particle sizes obtained from the XRD results using eqn (5) and (6). N₂O chemisorption results reveal that CZA_comm displays the highest Cu surface area in the series, followed by CZA and CZAZ. The same trend is obtained when using the particle sizes obtained from XRD, with CZAZGa displaying the lowest Cu surface area in the series.

#### Catalytic activity

Three different reactions were studied in this work, namely the synthesis of methanol (MeS), the direct synthesis of DME (DDMES) and the sorption enhanced DME synthesis (SEDMES). The MeS experiments were performed as steady-state experiment, and the SEDMES and DDMES experiments were performed in a transient mode, see Fig. 2. The final steady-state conversion level, after complete saturation of the zeolite adsorbent, was taken as the DDMES experiment. The prebreakthrough part of the experiment corresponds to the SEDMES. As an example, Fig. 2 shows the transient response for the CZA catalyst, identifying regions considered for reporting the performances of the SEDMES and DDMES modes. Although water is not removed previous to product analysis, product selectivity is reported on dry basis.

**Synthesis of methanol, MeS.** As shown in Fig. 3a, both CZA_comm and CZA record the highest CO and CO₂ conversions of ca. 7.6 and 9.9%, respectively. These conversions are
close to the equilibrium conversion values. Doping the catalysts with ZrO2 decreases CO conversion to ca. 1.6%, without affecting CO2 conversion. CZAZGa displays the lowest CO and CO2 conversions in the series, with negative CO conversion of ca. 10.6%, indicating that the content of CO in the outlet is higher than in the inlet. Negative conversion values indicate that CO is formed during the process via the r-WGS reaction, which is promoted by the addition of ZrO2 and especially Ga2O3 to CZA. Fig. 3b shows the outlet concentrations of CO2, CO and methanol for all catalysts. All catalysts show similar CO2 outlet concentration around 57% mole (the equilibrium value is 58.7% mole), but the concentration of CO increases in the order CZA_comm (32.2% mole) < CZA (34.4% mole) < CZAZ (36.8% mole) < CZAZGa (39.8% mole; the equilibrium value is 32.2% mole), confirming the higher ability of CZAZ and CZAZGa for the r-WGS reaction. Methanol production is higher over the non-promoted catalysts, i.e., CZA_comm (9.9% mole) and CZA (8.5% mole), decreasing over CZAZ (5.9% mole) and CZAZGa (3.1% mole) (9.1% mole at the equilibrium). A direct relationship between the outlet concentration of methanol and the Cu surface area of the catalysts obtained through N2O chemisorption can be observed (CZA_comm > CZA > CZAZ, see Table 1). This direct relationship between methanol production and Cu surface area has been also reported by other authors.25 In terms of TOF, a similar value of around $2 \times 10^{-3}$ s$^{-1}$ was obtained for these three catalysts. On the other hand, the activity trends shown in Fig. 3a and b reveal that even if the addition of ZrO2 and Ga2O3 increases the CO/CO2 ratio in the reactor, it does not result in higher methanol production. Martin et al. studied the synthesis of methanol over CZA commercial catalysts using different syngas compositions and concluded a CO2 concentration of ca. 2.4% in the syngas is the optimum one for the synthesis of methanol.9 The presence of a low amount of CO2 suffices to form methanol and water. The H2O formed activates the WGS reaction to produce more CO2, which is transformed to methanol. In this way, the production and consumption of H2O (eqn (2)) and CO (eqn (3)), the CH3OH to CO ratio can be taken as a good descriptor for the preferential reaction pathway on each catalyst. Thus, high CH3OH/CO ratios indicate that the catalyst is more active to methanol production than to the r-WGS reaction. Conversely, lower CH3OH/CO ratios indicate that the catalyst is more active to the r-WGS reaction. As shown in Fig. 3a, the CH3OH/CO ratio decreases in the order CZA_comm > CZA > CZAZ > CZAZGa, confirming the promotional effect of ZrO2 and Ga2O3 towards the r-WGS reaction.

**Direct dimethyl ether synthesis, DDMES.** As shown in Fig. 3c, the CO2 and CO conversions obtained in the DDMES are higher than during the MeS with all catalysts. This observation indicates that the production of DME from methanol (eqn (4)) shifts the syngas to methanol reactions (eqn (1) and (2)) towards the formation of CH3OH. All catalysts show similar CO2, principle is it possible to adjust the CO2/CO ratio in the syngas via the WGS reaction. The addition of Zr and Ga promoters to CZA catalysts improves CO2 adsorption on the catalyst and favours the r-WGS reaction thus increasing CH3OH production from CO2.18,29,29 Faen Song et al. found that a Zr load of approx. 3 mol% improves the dispersion of Cu and the adsorption of CO2 on the surface of the CZA, stating that higher values result in the sintering of Cu particles, and therefore a decrease of the catalyst activity.18 W. J. Lee et al. studied the addition of Zr, Mg and Ga to a commercial CZA catalyst20 and concluded that Zr favours the methanol production but lowers CO2 conversion.

We found that doping CZA with Zr or Ga oxides promotes the r-WGS, thus increasing the CO/CO2 ratio in the reactor. However, this effect does not lead to a higher methanol production with the doped catalysts. This can be explained by taking into account that CO2 transformation into CO via the r-WGS reaction results in the production of H2O (eqn (3)). The presence of H2O in the reaction medium is detrimental for the production of methanol from CO2 (eqn (2)) because it displaces the equilibrium towards the reactants. The outlet gas composition of the experiments with CZA_comm and CZA is close to the equilibrium composition (9.2% of CH3OH). However, methanol concentration below the equilibrium value is obtained with the doped catalysts, 5.9% with CZAZ and 3.1% with CZAZ-Ga. As shown above, CZAZ and CZAZGa display the lowest ZnO content in the series (see Table 1). ZnO plays a very important role in the performance of CZA catalyst as a structural promoter of the active phase.54-56 The presence of ZnO promotes the formation of small and stable Cu crystals on the catalyst, improves its dispersion and even promotes H2 dissociation under conditions of deficient adsorption of H2 on Cu particles, followed by H2 spillover to Cu.55 The N2O chemisorption data reveal that the catalysts with the highest ZnO loadings (CZA_comm and CZA) display the highest Cu surface areas (see Table 1), therefore showing the highest methanol production rates. Conversely, CZAZ and CZAZGa display the lowest Cu surface areas in the series, and consequently the lower methanol production rates. In addition, it is possible that by promoting the r-WGS reaction Cu particles in the latter samples tend to agglomerate due to the excess of H2O in the reaction medium.

Since CO2 is the source for both methanol (eqn (2)) and CO (eqn (3)), the CH3OH to CO ratio can be taken as a good descriptor to catalyse the preferential reaction pathway on each catalyst. Thus, high CH3OH/CO ratios indicate that the catalyst is more active to methanol production than to the r-WGS reaction. Conversely, lower CH3OH/CO ratios indicate that the catalyst is more active to the r-WGS reaction. As shown in Fig. 3a, the CH3OH/CO ratio decreases in the order CZA_comm > CZA > CZAZ > CZAZGa, confirming the promotional effect of ZrO2 and Ga2O3 towards the r-WGS reaction.
conversions, *ca.* 20%, with CZAZGa showing a slightly higher conversion of 23%. These conversion values appear to be above the equilibrium values, but it must be noticed that the equilibrium calculations have been carried out considering only CO, CO₂, H₂, H₂O, methanol and DME in the system. As stated before, traces of C₂H₄ have been observed in both DDMES and SEDMES experiments. If ethylene is included among the products, CO and CO₂ equilibrium conversions rise to *ca.* 100% and above 50%, respectively. This effect of the presence of C₂H₄ in the reacting system on the thermodynamics can explain why the outlet concentration of CO₂ surpasses the theoretical value. On the other hand, CO conversions below the equilibrium value (54%) are observed. Again, CZA_comm shows the highest CO conversion of 47.5% followed by CZA (40.5%), CZAZ (38.8%),

---

**Fig. 3** CO₂ and CO conversions, CH₃OH/CO or DME/CO-ratios and outlet mole concentrations of methanol (green bar), CO (red bar), CO₂ (blue bar) and DME (yellow bar), recorded during the MeS (a and b), DDMES (c and d) and SEDMES (e and f) processes under the following conditions: DDMES and SEDMES: 275 °C, 25 bar, 1080 h⁻¹, CO₂/CO = 2; MeS: 270 °C, 25 bar, 7500 h⁻¹, CO₂/CO = 1.9.
As observed, methanol and DME are produced over all catalysts, with \( \text{CZA}_\text{comm}, \text{CZA}, \) and \( \text{CZA} \) reaching DME outlet concentrations of 8.7\% mole, 7.2\% mole, and 6.8\% mole. Note that these values are slightly below the DME equilibrium concentration of 10.9\% mole at the conditions studied in this work. \( \text{CZA} \text{Ga} \) produced a very low amount of DME, with an outlet concentration of \( \text{ca.} 0.8\% \) mole, but shows the highest concentration of methanol of 5.7\% mole vs. \( \text{ca.} 4\% \) mole shown by the other catalysts (the equilibrium value for methanol composition is 3.8\% mole). Note that the combined production of methanol and DME with \( \text{CZA} \text{Ga} \) is the lowest in the series. The lower activity towards the production of methanol and DME in the catalytic bed with \( \text{CZA} \text{Ga}/\gamma-\text{Al}_2\text{O}_3 \) can be explained by the very high activity of \( \text{CZA} \text{Ga} \) for the \( \text{r-WGS} \) reaction, which results in a high content of \( \text{H}_2\text{O} \) in the reaction medium, which is known to deactivate both methanol production over \( \text{CZA} \) catalysts and methanol dehydration over \( \gamma-\text{Al}_2\text{O}_3 \). As explained above, we used the DME/CO outlet ratio as a descriptor of the preferential reaction pathway, DME production vs. \( \text{r-WGS} \) reaction, with the catalysts under study during the DDMES. In line with the trend observed above for the synthesis of methanol \( \text{MeS} \), all catalysts show a similar trend of DME/CO ratios of \( \text{ca. 0.4} \) (\( \text{CZA}_\text{comm} \)) and 0.3 (\( \text{CZA} \)), with \( \text{CZA} \text{Ga} \) showing the smallest ratio of 0.02, indicating a high \( \text{r-WGS} \) activity of this catalyst hence a higher CO selectivity.

**Sorption enhanced DME synthesis, SEDMES.** As shown in Fig. 3e, the SEDMES process results in significantly higher CO\( _2 \) conversions, \( \text{ca. 100\%} \), irrespective of the catalyst under study. The CO conversions with the \( \text{CZA} \) catalysts (\( \text{CZA}_\text{comm} 55\% \) and \( \text{CZA} 47\% \)) are higher than in the other process, but the ones recorded with \( \text{CZA} 17\% \) and \( \text{CZA} \text{Ga} (–56\%) \), especially the latter, are lower than the ones recorded during the DDMES and \( \text{MeS} \). DME and methanol are produced with all catalysts. DME production is significantly higher than that obtained in the DDMES process, with outlet concentration values of 70\%, 66\%, 54\%, and 23\% mole for \( \text{CZA}_\text{comm}, \text{CZA}, \text{CZA} \), and \( \text{CZA} \text{Ga} \), respectively (Fig. 3f). All of these values are well above the aforementioned DME equilibrium concentration of 10.9\% mole. The significantly higher CO and CO\( _2 \) conversions (above equilibrium) and DME production reveal the promotional effect of water removal with zeolite 3A during the direct DME synthesis from syngas.

The \textit{in situ} removal of \( \text{H}_2\text{O} \) during the SEDMES process exacerbates the different performances between the catalysts with high activity for the production of methanol (\( \text{CZA}_\text{comm} \) and \( \text{CZA} \)) and the ones with high activity for the \( \text{r-WGS} \) reaction (\( \text{CZA} \) and \( \text{CZA} \text{Ga} \)). DME production is favoured over \( \text{CZA} \) and \( \text{CZA}_\text{comm} \), indicating the higher catalytic activity of these catalysts for the reactions in which methanol and DME are produced, eqn (2) and (4), respectively. On the other hand, since the \( \text{r-WGS} \) reaction (eqn (3)) is faster than methanol production over \( \text{CZA} \text{Ga} \), water removal promotes further the production of CO from CO\( _2 \), resulting in negative CO conversion values, which is an indication that the rate of methanol production from CO (eqn (1)) is very slow.

Finally, it is worth mentioning that the CO\( _2 \) concentration in the products in SEDMES is very low (<4\%) for all catalysts, which is very important for the DME/CO\( _2 \) separation process downstream. These low CO\( _2 \) outlet concentrations suggest that the SEDMES process could be also successfully applied the direct synthesis of DME from pure CO\( _2/\text{H}_2 \) syngas.

**Conclusions**

In this work, we have studied the performance of a series of \( \text{CZA} \) catalysts for the synthesis of methanol and the direct synthesis of DME (using \( \gamma-\text{Al}_2\text{O}_3 \) as acid catalyst) from a CO\( _2 \)-rich syngas, akin to that obtained from the gasification of biomass. In order to adjust the CO/CO\( _2 \) ratio within the reactor, \( \text{CZA} \) has been doped with Zr and Ga oxides. This strategy allows to increase the CO/CO\( _2 \) product ratio, but it fails to increase methanol production probably due to the higher ability of the doped catalysts for the \( \text{r-WGS} \) reaction and the concomitant production of \( \text{H}_2\text{O} \), which results in the loss of activity of the doped \( \text{CZA} \) for the production of methanol from syngas. In addition, being a reaction product, the presence of water in the reaction medium prevents the production of methanol from syngas and the production of DME from methanol. In order to remove \( \text{H}_2\text{O} \) during the direct synthesis of DME from CO\( _2 \)-rich syngas we have placed an \( \text{H}_2\text{O} \) sorbent solid, zeolite 3A, in the reactor. This strategy, referred to as sorption enhanced DME synthesis (SEDMES), allows to shift the equilibria to the product side, thus resulting in higher carbon conversions and DME productions. In fact, a DME concentration of \( \text{ca. 70\%} \), well above the equilibrium value, was obtained with the non-doped \( \text{CZA} \) catalysts, which show the highest production of methanol from CO\( _2 \) rich syngas. On the other hand, water removal during the SEDMES with the Zr and Ga doped catalysts lead to a high production of CO.
