A B S T R A C T

2D semiconducting nanosheets of Transition Metal Dichalcogenides are attractive materials for solar energy conversion because of their unique absorption properties. Here, we show that Mo thio- and oxo-thio-complexes anchored on 2D p-WSe$_2$ nanosheets considerably boost water splitting under visible light irradiation with photocurrent density up to 2.0 mA cm$^{-2}$ at -0.2 V/NHE. Besides developing high electro-catalytic activity, the Mo-complexes film is also shown to be capable of healing surface defects. We propose that the observed healing of surface defects arises from the strong adsorption on point defects of the 2D WSe$_2$ flms as supported by DFT calculations. In addition, the thio-, oxo-thio-Mo complexes films are shown to enhance charge carrier separation and migration favouring the hydrogen evolution reaction, putting forward the use of thio-, oxo-thio-Mo complexes as a multicomponent passivation layer exhibiting multiple properties.

1. Introduction

Two-dimensional transition metal dichalcogenide (2D TMDC) materials [1,2] are building blocks of great interest for solar energy conversion [3–6] because of their unique high light absorption properties [7]. While bulk materials possess large optical absorption greater than 10$^6$ m$^{-1}$ across the visible range, MoS$_2$ monolayer possessing a thickness of ~0.8 nm was shown to absorb more than 10% of light [7,8]. TMDC films have thus been considered for various applications including ultrathin, flexible photovoltaic devices [1,2] and photo-electrochemical hydrogen production devices [5,6]. The hydrogen evolution reaction (HER) was previously observed on 2D WSe$_2$ under visible irradiation with Pt as a water reduction co-catalyst [5]. Considerable improvement of the photocurrent was recently achieved with an optimized Pt-Cu co-catalyst combined to defects passivation treatments [6]. Nevertheless, to make viable a large scale development of this technology, it is mandatory among others to replace precious metal catalysts with more earth-abundant materials for instance using TMDC catalysts [9,10].

Because of the ultrathin thickness of the 2D materials, small sized catalysts such as single atoms [11] or molecular catalysts are well suited to activate the 2D photo-electrodes. Besides perfect size matching, environmentally benign, low-cost (noble metal free), molecular catalysts are perfectly suited for these 2D materials because their small size facilitates their infiltration into the layered 2D materials. Among molecular complexes, hydrogenase and nitrogenase enzymes with active centres consisting of Fe, Ni and Mo are nature effective catalysts for the HER [12,13]. Indeed, Mo$_2$S$_4$ based nanomaterials including molecular [14–17], nanoparticulates [18,19], nanoflakes [20,21], nanosheets [22,23] and amorphous films [24–26], were previously proposed as HER catalysts. Although previously reported MoSx amorphous film catalysts displayed thicknesses around 40–50 nm [26], molecularly thin films of lower thickness are best suited for photocatalytic applications since they minimize light shielding. Molecular Mo...
complexes including MoS$_2$ [14], (MoS$_2$)$_3$$^2$− [16], (MoS$_2$)$_3$$^2$+ [15], were recently developed as catalysts for the HER because they represent earth abundant alternatives for large-scale use in place of noble metal catalysts. While very few works have reported on the catalytic activity of oxo-thio complexes [27–29], Mo thio clusters yielding high catalytic efficiency for the HER have been designed to molecularly mimic the MoS$_2$ edge sites. In addition, these thio-Mo complexes have proven to display reasonable HER stability in acidic solution [15,16]. Thus, these complexes represent ideal candidates to be coated onto 2D photoactive materials such as 2D TMDCs.

Synthetic or processing routes of these complexes were largely developed in solvents such as dichloromethane [14], methanol [15] or DMF [16]. In the context of the sustainable generation of hydrogen, it is highly desirable to perform the synthesis and to process the Mo complexes in water and open air. The development of a precious metal-free catalyst, which is also stable and active in aqueous environments [30] has been recently identified as a long term goal for the HER. One of the challenges to face during all-aqueous synthesis and film forming is the selection of photoactive species from a distribution formed at a given pH, as a consequence of the numerous equilibrium reactions usually occurring in H$_2$O. Moreover, due to hydrolysis which occurs inevitably in highly alkaline H$_2$O medium, the resulting complexes distributions include both thio and oxo-thio-complexes [31]. While catalytic cycles for the HER on this Mo complexes or clusters were largely documented [14–17], very few studies [27–29] reported on the efficiency of oxo-thio groups on HER. Although the catalytic mechanism reported for the Mo = O groups in MoSx amorphous films catalysts [28] involves some redox reactions occurring on the unsaturated Mo sites (Mo(V) + e = Mo(IV)) [32] thus requiring applied cathodic voltage, a recent work [28] argues that the redox reactions of the HER mechanism involve S$_2$2− anions. Assessment of the photocatalytic activity of these Mo thio complexes for the hydrogen evolution reaction particularly when operating without any applied cathodic voltage should therefore contribute to shed light onto the involved catalytic mechanism.

Increase of the durability of complex catalysts while minimizing their catalytic deactivation represents another crucial challenge for the large-scale development of these catalysts. Chemical bonding implementation between the complex catalyst and the photoelectrode substrate can prevent complexes desorption [33]. One possible approach is to anchor Mo complexes onto the WSe$_2$ photo-electrode via ligand interactions. While internal edge defects such as tears and pinholes can serve as anchoring sites onto the 2D materials [34], this strategy may involve some terminal chemical units of the Mo complexes. This will require a specific design of the Mo complexes in order to preserve the active sites density, ensuring their long term catalytic efficiency. Lastly, another important challenge to face is defects passivation [3,35] when promoting these 2D nanosheets photocathodes. Defects’ healing greatly reduces photo-generated charge carriers’ recombination thus enhancing the photo-electrodes performances. It is therefore of great interest to explore innovative passivation routes, tackling surface defects of the 2D materials interacting with terminal sulfides, or, di-sulfides units of the thio and oxo-thio Mo complexes.

In this work, we propose new water-stable Mo thio complexes as photocatalysts for the hydrogen evolution reaction (HER) in water splitting under visible irradiation. In the context of low cost fabrication, WSe$_2$ electrodes were fabricated by a simple process route including deposition of solvent-exfoliated WSe$_2$ nanosheets by drop casting onto a FTO substrate. The Mo thio complexes were then impregnated onto the WSe$_2$ electrodes via a solvent-free film forming process. Anchoring of the Mo-based molecular catalyst is achieved by selection of the most interactive thio-, oxo-thio-Mo complexes. This involves ligand solution interactions between W(IV) cation or surface defects of the photo-electrode and S$^2$− or S$_2$2− anions of the thio-thio complexes catalyst. The resulting films are composed of a mixture of thio and oxo-thio Mo complexes, the latter being inevitably formed in alkaline aqueous medium. A catalyst film structure is proposed mainly resulting from i) the identification of the Mo complexes in solution by mass spectroscopy (ESI-MS), ii) the collection of XPS data from the resulting catalyst solid film and iii) Density Functional Theory (DFT) calculations of the probable conformations of the Mo thio and oxo thio Mo complexes anchored on WSe$_2$ photo-electrodes. The unique characteristics of thio and oxo thio Mo complexes as healing, anchorable catalysts for the photocatalytic HER on 2D materials are detailed herein. These experimental observations are supported by DFT calculations providing insights into (i) the probable binding developed between the surface defects of the 2D materials and the Mo thio and oxo-thio complex catalysts; (ii) the thermodynamics of H$^+$ adsorption and H$_2$ desorption on the thio, oxo-thio complexes by means of HER free energy $\Delta G_{H2}$ calculations as proposed by Nørskov et al. [36].

2. Experimental section

2.1. Preparation of electrodes and catalyst deposition

2.1.1. 2D WSe$_2$ – FTO electrode fabrication

As-received WSe$_2$ powder (WSe$_2$ 99.8 % metal basis from Alfa Aesar) was exfoliated in dichlorobenzene solvent (DCB, Aldrich) using an ultrasonicator (Bibloec Scientific, 750 W). 3 g of WSe$_2$ was exfoliated at 40 % amplitude (6 s: on / 4 s: off) for 16 h in a 4 °C bath. After selection by centrifugation at 1500 rpm, removal of soluble impurities and transfer in dimethylformamide solvent (DMF) of the WSe$_2$ nanosheets were performed by a series of ultracentrifugation / redispersion. Typically, the DCB dispersion containing the WSe$_2$ nanosheets was ultracentrifuged at 16,000 rpm and the solid redispersed in 20 ml DMF. A simple procedure was used to fabricate the WSe$_2$ films. Fluoride doped Tin Oxide (F: SnO$_2$ or FTO) coated glass substrates (SOLEMS, France) were coated by drop casting the WSe$_2$ nanosheets (7.5 g l$^{-1}$ WSe$_2$). After drying by air evacuation at room temperature, a total of 1.5–2 g cm$^{-2}$ of WSe$_2$ were deposited in 3 successive coatings. The WSe$_2$-FTO electrodes were calcined at 350 °C – 2 h under Ar before performing the catalyst deposition. A BET surface of ∼ 2 m$^2$ g$^{-1}$ was determined on powder collected from films deposited on calcined electrodes.

2.1.2. Mo thio and oxo thio complexes aqueous solutions preparation

Ammonium tetra-thio-molybdate (NH$_4$)$_2$MoS$_4$ Sigma Aldrich) (0.65 g, 2.5 mmole) was dissolved in 0.31 M aqueous ammonium sulfide solution (prepared from (NH$_4$)$_2$S 20 % wt in H$_2$O, Sigma Aldrich) (8 ml, 2.5 mmole). Subsequent polycondensation of the species is performed by pH adjustment (pH 9.00) by addition of 0.5 M HCl (4.5 ml) and the solution is volumed at 25 ml. After aging at 25 °C during 2 h, the solution is diluted to 250 ml by H$_2$O. Solid precipitate (in very little quantity) is removed by ultracentrifugation at 16 000 rpm 10 min and the molecular Mo thio complexes are collected in the supernatant. The molar ratio of S$^2$− to Mo, S/Mo is 5, and the Mo concentration is Mo = 0.01 M.

2.1.3. Co-catalyst deposition by selective dip coating impregnation

Selective dip-coating of the co-catalyst was performed by vertically immersing the WSe$_2$-FTO electrode into the Mo thio complexes co-catalyst solution. The electrode was kept in contact with the co-catalyst solution for 6 h (or 16 h) under gentle stirring at room temperature. The electrode was then washed by dropping the electrode into deionized water without stirring for 5 min. A typical sequence includes the three following steps: 1) 16 h impregnation– 5 min washing– 10 min heat treatment at 110 °C. 2) 16 h impregnation – 5 min washing– 10 min heat treatment at 110 °C. 3) 6 h impregnation – 5 min washing- 10 min heat treatment at 110 °C.

2.2. General characterization

2.2.1. Co-catalyst deposition by selective dip coating impregnation

Selective dip-coating of the co-catalyst was performed by vertically immersing the WSe$_2$-FTO electrode into the Mo thio complexes co-catalyst solution. The electrode was kept in contact with the co-catalyst solution for 6 h (or 16 h) under gentle stirring at room temperature. The electrode was then washed by dropping the electrode into deionized water without stirring for 5 min. A typical sequence includes the three following steps: 1) 16 h impregnation– 5 min washing– 10 min heat treatment at 110 °C. 2) 16 h impregnation – 5 min washing– 10 min heat treatment at 110 °C. 3) 6 h impregnation – 5 min washing- 10 min heat treatment at 110 °C.

2.2. General characterization

2.2.1. Co-catalyst deposition by selective dip coating impregnation

Selective dip-coating of the co-catalyst was performed by vertically immersing the WSe$_2$-FTO electrode into the Mo thio complexes co-catalyst solution. The electrode was kept in contact with the co-catalyst solution for 6 h (or 16 h) under gentle stirring at room temperature. collected using a Xevo G2 Q ToF MS instrument equipped with an electrospray (ESI) source supplied by Waters. X-ray Photoelectron Spectroscopy was performed on a ThermoScientific K-Alpha system with monochromatic Al Kα (hv = 1486.6 eV). All the XPS spectra were calibrated with C 1s at 284.6 eV (± 0.1eV). TEM studies were carried out using a JEOL JEM-ARM200F spherical-aberration probe corrected electron microscope equipped with a cold field emission gun operated at 200 kV and an ultrafast Ultracen 2k x 2k camera (Gatan) for TEM.

2.3. Photo-electrochemical and hydrogen characterization

2.3.1. Photoelectrochemical characterization

The electrodes (S = 1 cm²) were evaluated in a three-electrode set up (Gamry Potentiostat) with an Ag/AgCl reference electrode and a Pt counter electrode. Photocurrent measurements were performed in 0.5 M H₂SO₄ aqueous electrolyte under chopped light. The light source (Oriel Instruments, LSC 100) used in the PEC measurements was equipped with a 100 W Xe lamp including AM1.5 G filter. An irradiance of 1 sun was achieved by adjusting the distance between the sample and the simulator and finely controlled using a pyranometer (PMA 2144 Solar light). Incident-photon-to-current-efficiency (IPCE) measurements of the photocathodes were performed illuminating the photocathode using a set of high-power light emitting diodes (H2A1 Series LED) from Roithner Laser Technik.

2.3.2. Hydrogen measurements using gas chromatography

A closed photo-electrochemical cell equipped with a three-electrode set-up was used for the hydrogen detection. An argon flow rate was injected into the cell in order to transport the evolved hydrogen from the photo-electrochemical cell to the Gas Chromatograph (Shimadzu, GC-2014 AT) allowing the real-time analysis of the composition of the gas generated inside the cell.

3. Results and discussion

3.1. Synthesis and characterization of a large variety of water-soluble thio and oxo-thio Mo complexes distributions

Mo(VI) is reduced by S²⁻ with formation of sulfur-rich, polynuclear, di-sulfido complexes [37] in aqueous solutions. Using (MoS₄)²⁻ as a Mo (VI) source salt and H₂O as solvent, we have explored a large range of water-soluble, thio and oxo-thio complexes by variation of the polycation dissociation degree (from pH 8 to pH 9.7) and of S²⁻ concentrations (S²⁻ / Mo mole or S/Mo mole = 4, 5 and 6, S and Mo denote respectively the total concentrations of sulfides and Molydenum species). As a result of the various oxo reduction reactions involved in aqueous sulfide solutions, (MoVI) + 2 e⁻ → MoIV, Mo(VI) + MoIV > 2 Mo(VI), the synthesized Mo thio and oxo-thio complexes solutions displayed Mo cations with various oxidation states including Mo(VI), Mo(V) and Mo(IV). Species formed in each solution were rationally displayed Mo cations with various oxidation states including Mo(VI), Mo(V), Mo(IV), the synthesized Mo thio and oxo-thio complexes solutions were clearly identified by ESI-MS in so-

3.2. Electrocatalytic properties of the thio-, oxo-thio-Mo complexes distributions

Electro-catalytic properties of films prepared from a large variety of complexes solutions (Mo = 0.01 M, 4 ≤ S/Mo ≤ 6, 8.0 ≤ pH ≤ 9.7) were first explored on FTO substrate. The whole set of water-soluble Mo thio and oxo-thio complexes, pH 8.0 ≤ pH ≤ 9.7, including solutions mainly composed of Mo monomers was shown to exhibit reasonably good electrocatalytic properties when deposited on FTO substrate (Fig. S3) with an average overpotential of 260 mV at j = 10 mA cm⁻². Finer inspection of the current density – potential curves in the low cathodic potential range, −0.2 V < E vs NHE < +0.0 V, reveals slightly better electrocatalytic properties of the films when prepared from complexes solution in the pH window, 8.8 ≤ pH ≤ 9.2 (Fig. S3). These slightly better catalytic properties are achieved from solutions made up of predominant species composed of Mo monomers (Mo₅S₄)⁴⁻, (Mo₅S₄)⁴⁻ and poly-condensed species possessing two or three Mo centres including (Mo₅S₄O₃)⁴⁻, (Mo₅S₄)⁴⁻ and (Mo₅S₄O)⁴⁻ clearly identified by ESI-MS. In contrast, slightly lower electrocatalytic properties were observed on films prepared from high pH solutions mainly composed of monomers such as (Mo₅S₄)⁴⁻ and (Mo₅S₄O)⁴⁻. To clarify the respective contributions on the catalytic performances of the thio and oxo-thio complexes, DME dispersions of pure (Mo₅S₄)⁴⁻ complexes were prepared following a procedure previously described [16]. Properties of these pure (Mo₅S₄)⁴⁻ complexes were investigated on films deposited on FTO substrates by drop casting. Let us recall that a value of η = 175 mV at j = 10 mA cm⁻² was previously reported in the literature [16] for the (Mo₅S₄)⁴⁻ thio complex in addition to graphene. Without any graphene addition and in our experimental conditions, i.e. on WSe₂ electrodes, similar over-potential values were
recorded at \( j \approx 10 \text{ mA cm}^{-2} \) in a large range of mass loadings for the pure (Mo\(S_{12}\)) complex as well as for our thio-, oxo-thio Mo catalysts (Fig. S4). Thus, our results show that films prepared from our thio-, oxo-thio- complexes display electrocatalytic properties for the HER similar to the (Mo\(S_{12}\)) complex. Although recent works on single-atom catalysts have shown superior activity \([11,46]\), we can point out that our Mo-thio, oxo-thio complexes possess catalytic activities comparable to the best Mo-S based catalysts (Table S3-1).

Using solvent-exfoliated, p-type WSe\(_2\) nanosheets, a significant decrease of the electrocatalytic activity is observed for films formed by deposition-evaporation or drop casting onto WSe\(_2\) (Fig. 2) substrates compared to films deposited onto FTO (Fig. S3). More specifically, this decrease is clearly observed in the mass loading range of 125–500 nanomoles cm\(^{-2}\) for complex solutions displaying a higher content of monomers (pH > 9.25) or prepared in the lower pH range (pH < 8.5). For films drop casted onto WSe\(_2\) electrodes, the best electrocatalytic activities were recorded for electrodes formed from solutions prepared in the pH range, \( 8.5 < \text{pH} < 9.25 \). As we previously reported, this pH range corresponds to the predominance domain of Mo dimers or trimers. XPS data performed on the corresponding dried films indicate a significant decrease of \( \sim 30\% \) of the terminal sulfide ratio, \( r_{\text{S-ter}} \), compared with films drop casted on FTO (Fig. 3a). This reveals that the observed decrease of \( r_{\text{S-ter}} \) probably arises from ligand interactions between terminal S\(^2^-\) or S\(^6^-\) anions of the thio or (oxo) thio complexes and W(IV) cations or surface defects of the 2D WSe\(_2\) substrate. This ligand interaction involving terminal S\(^2^-\) or S\(^6^-\) thus drastically decreases the available S\(^2^-\) or S\(^6^-\) catalytic sites concentration of the films prepared from high pH dispersions and accounts for the lower catalytic activity of films mainly composed of monomers. In contrast, the relatively higher concentration of (Mo\(S_{12}\))\(^2^-\), (Mo\(O\))\(^2^-\) and (Mo\(S_{3}\)(O))\(^2^-\) complexes allows one to preserve a reasonably high concentration of active catalytic sites in the optimal pH range.

![Fig. 1. Typical ESI-MS spectra recorded on Mo thio complexes solution prepared at pH 9.00 and S/Mo = 5. (b) Species predominance diagram determined at 0.01 M Mo and S/Mo = 5 from ESI-MS data showing concentration peaks for (Mo\(S_{12}\))\(^2^-\), (Mo\(O\))\(^2^-\) and (Mo\(S_{3}\)(O))\(^2^-\) complexes between pH 8.5 and pH 9. Insert: Dependence of [Mo\(_1\)]/[Mo\(_{\text{total}}\)] and [Mo\(_3\)]/[Mo\(_{\text{total}}\)] with pH. [Mo\(_1\)]/[Mo\(_{\text{total}}\)] and [Mo\(_3\)]/[Mo\(_{\text{total}}\)] denote respectively the ratio of Mo monomers, [Mo\(_1\)]/[Mo\(_{\text{total}}\)] = Mo monomers/(Mo monomers + Mo polymers) and the ratio of Mo polymers, [Mo\(_3\)]/[Mo\(_{\text{total}}\)] = Mo polymers / (Mo monomers + Mo polymers). Mo monomers detected by ESI MS mainly include (Mo\(S_{2}\))\(^2^-\), (Mo\(O\))\(^2^-\).

![Fig. 2. Electrochemical and photo-electrochemical characterization of thio-, oxo-thio- Mo complexes films prepared at S/Mo = 5 and at various pH in H\(_2\)SO\(_4\) 0.5 M. (Top a-c): J-E curves (a pH 8; b pH 9; c pH 9.5) recorded under intermittent illumination on films prepared by evaporation-drying (or drop casting) onto WSe\(_2\) electrodes (blue curves). J-E curves of corresponding films prepared on bare WSe\(_2\) electrodes are given as control (black curves). (Down d-f): J-E curves on films prepared by selective dip coating on WSe\(_2\) electrodes, impregnation time: 2 × 16 h. The electro-activities of the films can be tracked from the curve sections recorded in the dark. 3.3. Thio- oxo-thio-Mo complexes as healing catalysts for solar to hydrogen conversion

The photo-electrochemical performances of the Mo thio complexes -WSe$_2$ electrodes were first assessed on electrodes prepared by drop casting under intermittent illumination (1 sun, 100 mW cm$^{-2}$). Note that all the species included in the MoS$\delta$y complexes solution are deposited by evaporation-drying in this film forming process. Low photocurrents were recorded by linear scanning voltammetry (LSV) for the whole set of films prepared in a large range of catalyst loading, 30 nanomoles cm$^{-2}$ $< n < 200$ nanomoles cm$^{-2}$ (Fig. 2). In spite of the high electro-

activity of the MoS$\delta$y catalyst films (Fig. 54), the low photocurrent detected suggests a large charge carrier recombination, probably arising from the large concentration of surface defects usually reported for 2D materials [35,47,48].

In view of the large variety of these Mo complexes distribution solu-
tions, each of which itself being composed of several thio and oxo thio complexes, an interesting approach would be to select the most inter-

active species taking benefit of the “WSe$_2$-thio complexes” interactions developed in solution. Thus, we have focused on a film forming process favouring the anchorage of thio- and oxo-thio-Mo complexes develop-

ing high complexing interactions and high catalytic performances. Similar to a strategy previously proposed to enhance the long term stability of (molybdenum sulfide clusters-defective graphene) catalyst involving S-C covalent bonding [33], chemical bond formation between thio or oxo-thio complexes and WSe$_2$ surface should contribute to im-

prove anchoring of the thio-complex catalysts onto the photo-electrode. More importantly, strong bonding formation between the thio complex ligands and surface defects of WSe$_2$ 2D material may help to heal these defects thus improving the optoelectronic performances of the 2D ma-

terials. A film forming process (denoted afterwards selective dip-

coating) was thus explored involving successive dip coatings with long duration time (up to $2 \times 16$ h) and followed by H$_2$O washing. Interest-

ingly, for dispersions displaying a well-defined range of S/Mo values and polycrystallization ratios (or pH), much larger photocurrents were recorded on dip-coated photo-electrodes compared to drop casted films for the large range of film thickness investigated, 50 nanomoles cm$^{-2}$ $\leq n \leq 750$ nanomoles cm$^{-2}$ (Fig. 2). In contrast to the film prepared by eva-

poration (or drop casting) which involves the whole set of thio com-

plexes species present in the solution, the better performances of the dip coated films were achieved from a selection of the most catalytically active complexes, mainly driven by the “ligand – WSe$_2$ photoelectrode” interactions acting in the solution during the dip coating process. Sev-

eral results demonstrate this complexes selection. First, significant differences are observed between the films prepared by drop-casting on FTO vs dip-coating on WSe$_2$ substrates. Optical and electronic micro-

scope images show formation of dendrite-like acicular particles (Fig. SSa) only visible on FTO, suggesting a phase separation during this film forming process by evaporation-drying, not observed in dip-coated samples. In addition, the main Raman peak recorded on these acicular particles at 400 cm$^{-1}$ (Fig. SSc) is not observed on films spectra prepare-

d on WSe$_2$ photo-electrodes. Second, a slow and progressive in-

crease of the photocatalytic activity is observed with increased time duration clearly recorded throughout the first 32 h of dip coating (Fig. S6). For the film withdrawn after the first hours of dip coating ($t < 4$ h), XPS data recorded on the corresponding films highlight a peak concentration of the oxo-thio-complexes ($f_{\text{MoOS}} = (\text{MoOS})/(\text{MoOS} + \text{MS}^{\text{mo}}) = 0.40$), probably arising from preferred deposition of (MoOyS$z$)$z$ monomers present in larger proportion in the solution. At longer dip coating duration times, changes in the film composition are clearly observed, illustrated by a decrease of the Mo-oxysulfide concentra-

on ($f_{\text{MoOS}} = 0.31$) and an increase of the S/Mo ratio (from S/ Mo = 4.2–4.6) indicating the selection of complexes at high S/Mo ratio. Various driving forces may cause the changes observed in the film composition. In the first stage of dip coating, selection of the thio, oxo-

thio-Mo complexes may be dictated by adsorption energies or by the complexation stability constants implying the thio-Mo complexes and the surface entities of the bare WSe$_2$ photo-electrodes. In a second step, the film formation process involves a change in the assembly pathway based on the interactions between the thio-, oxo-thio- Mo complexes and the first layers of Mo sulfide oligomers anchored on the WSe$_2$ photo-electrode surface. In addition, consistently with this selection process, the best photocatalytic activities were achieved with dip coatings alternated to desorption stages, favouring the removal of less interactive species before a subsequent impregnation. Lastly, significant differences both of S/Mo and $f_{\text{ter}}$ ratios are observed on final film compositions between drop casted and dip coated Mo complexes-coated WSe$_2$ electrodes. More particularly, Fig. 3a reveals a selection of high S/Mo ratio complexes including probably a higher content of (Mo$_2$S$_{12}$)$z$ complex in films achieved by selective dip coating compared to a drop coating process.

From a rationale screening of the photocatalytic activities performed on a large set of films ($4 \leq S/Mo \leq 7$ and $8.0 \leq pH \leq 9.7$), best photocatalytic performances were observed for dip coated films fabricated from solutions at S/Mo = 5 and in the optimum pH range, 8.75 $\leq pH \leq 9.25$. More interesting, without the use of any passivating additive, much higher photocurrents were achieved after impregnation with the Mo thio complexes catalysts compared to noble metal catalyst
such as Pt-Cu [6]. Although the two catalysts exhibit similar electroactivity as revealed from the dark currents, a larger photocurrent of 2.5 mA cm$^{-2}$ is recorded for the WSe$_2$ photocathode after Mo thio complexes activation versus 0.4 mA cm$^{-2}$, when activated by Pt-Cu (Fig. 4a). Likewise, note that no significant photocurrent was observed after deposition of MoS$_2$ nanocrystals catalyst prepared by a method previously reported in the literature [49]. Because Pt-Cu and MoS$_2$ nanocrystal catalysts are well known to greatly facilitate electron transfer [6], the large photocurrent improvement observed with Mo thio complexes could be assigned to a drastic decrease of recombination centres density.

In addition, while photocurrent recorded from bare WSe$_2$ photoelectrode exhibits current spikes typical of charge recombination and/or accumulation (positive spikes), such behaviour is completely inhibited for co-catalyst coated WSe$_2$ photoelectrodes (Fig. 4b). Indeed, after the deposition of the thio-Mo complexes, the significant decrease of this transitory photocurrent is assigned to a better charge transfer efficiency $\eta_d$ defined as $\eta_d = I_{0,0}/I_{0,0}$, where $I_{0,0}$ is the steady state current corresponding to an effective net photo-current; $I_{0,0}$ is the current just after light commutation before any recombination. We can also notice a similar slope of the $i(v)$ curves recorded under dark or under illumination for the bare WSe$_2$ photo-electrode. In contrast for co-catalyst coated WSe$_2$ photo-electrode, a different slope is clearly observed on the $i(v)$ curve sections recorded under dark or under illumination. This slope increase is likely related to a decrease of the recombination rate together with an activation of the charge transfer. This charge transfer improvement highlighted from these LSV curves clearly reveal the healing effect provided by these thio-Mo-complexes.

An additional evidence for defects passivation was obtained from photoluminescence. Room temperature photoluminescence (PL) characterization was performed on two WSe$_2$ photo-electrodes with and without Mo thio-complexes catalyst impregnation. While no photoluminescence was recorded on the catalyst-free sample, we clearly observe a peak of the PL at 1.43 eV on the sample coated by the Mo-thio-complex (Fig. 4c). Because low photoluminescence intensity in these materials is usually attributed to defect-mediated non-radiative recombination [35], the observed decreased recombination probability of photo-induced electrons and holes results from surface defects passivation by the thio-, oxo-thio-Mo-complexes.

To demonstrate that the recorded photocurrent could be ascribed to the hydrogen formation, we have measured the real-time hydrogen evolution by gas chromatography using a closed photo-electrochemical cell (See Supp. info). Under constant illumination, using a Pt calibration cell (Pt foils both as working and counter electrodes) and assuming a Faradic efficiency of 100% for the Pt calibration device, we determined a Faradic yield around 97%.

In order to evaluate the photochemical performance of the photo-electrode, we have performed incident-photon-to-current-efficiency (IPCE) measurements. Fig. 5a shows the comparison between photon absorption and IPCE spectra as a function of illumination wavelength. We measured a sizeable IPCE value in the whole wavelength range investigated from 810 to 490 nm (1.53 eV–2.53 eV), with a maximum of 9% at $\lambda = 760$ nm (1.63 eV), corresponding to the excitonic peak.
For shorter wavelengths illumination, despite the higher photon absorption a levelling off of the IPCE value is observed. We tentatively ascribed this effect to either a non-optimum charge carrier collection or to an increased surface recombination of the photo-generated carriers at these wavelengths due to their shorter penetration lengths. Concerning the bare photo-electrode without co-catalyst, very low IPCE values around values 0.2 % were measured in the whole spectrum range (Fig. S7). This shows the remarkable beneficial effect of the co-catalyst on the photocathode’s efficiency.

3.4. Co-catalyst film structure, composition and properties

Typical SEM cross section image of the co-catalyst – WSe₂ film recorded after sequential slicing using FIB (Fig. 3b) shows an interconnected network of anisotropic WSe₂ nanoflakes. Presence of continuous, curved domains at inter-nanoflakes junctions indicates the coating of the WSe₂ nanoflakes by the co-catalyst film.

To get better insight into the co-catalyst - WSe₂ photoelectrode morphology, HRTEM was performed on the coated photo-electrodes samples. Characterization of samples before and after HER did not reveal significant changes in the film microstructure. Typical HRTEM images (Fig. 3c) reveal an ultrathin amorphous film displaying irregular thicknesses ranging from 2 to 10 nm coating the well-crystallized 2D nanoflakes. The well-crystallized nanoflakes were unambiguously identified as WSe₂ from the lamellar structure displayed by the nanoflakes, in addition to the (Se/W)₆₅₃ = 2 ratio value determined by EDS. Although an accurate determination of the S/Mo ratio is relatively tricky because of the overlap of the Lα (2.928 keV) and Kα (2.307 eV) energy peaks, S and Mo were nevertheless detected as major elements from the amorphous ultrathin film thus allowing full identification of the amorphous coating to the co-catalyst film. The low amount of the Mo thio-ox-thio catalyst deposited on the WSe₂ photo electrode revealed by HRTEM investigation was quantitatively assessed by Inductive Coupled Plasma measurements. After sonication and concentration of eight high performance electrodes (S/Mo = 5, pH 8.75, dip coated 2 × 16 h) in 10 ml NaOH 0.1 M solution, the loaded amount was measured to be 100–150 Mnano moles cm⁻². With the assumption of a full coverage of the surface area of the 2D material including the basal plane and a head surface of 0.5 nm² for the Mo complexes, the average film thickness is thus determined to be four to ten monolayers. These results suggest that when discussing the catalytic performances of the film, the properties of free-standing Mo complexes need to be taken into account together with the particular thio- and oxo-thio-Mo complexes species anchored onto the WSe₂ substrate.

Regarding the co-catalyst film composition, Fig. S8 shows the Raman spectrum recorded on high performance films prepared from solutions fabricated at S/Mo = 5 and in the pH range 8.75 < pH < 9.25. Although these films possess a S/Mo = 4.6, Raman signatures including those previously recorded on isolated (MoS₂)²⁻, (Mo₅S₁₃)²⁻, (Mo₇S₅O)²⁻ and (Mo₆S₅O₂)²⁻ molecular structures. These building blocks could be present (i) in high interaction with the WSe₂ photo-electrode surface or (ii) arranged into a partially reticulated network to form a continuous, mechanically stable film but with an important ratio of free terminal disulphide groups (iii) or as isolated oligomers as suggested by the high Δtₚₑ value determined from XPS data.

Concerning the film formation, we propose that the co-catalyst film results from the conversion of the thio-, oxo-thio-Mo oligomers into an amorphous polymeric phase. Several mechanisms could be proposed: i) The formation of an oligomer-based coordination polymer involving interactions between the sulphide –disulphide groups and the Mo centres [32]. Indeed, the coordination-reticulation of the polymer is promoted by the various oxidation states displayed by the Mo centres as shown by XPS ii) Oligomer-induced hetero-nucleation and growth as previously observed in the preparation of metal organic framework [50]. To account for the experimentally observed change of S/Mo ratio in our co-catalyst films with dip coating time duration (S/Mo aym = 4.2 -> 4.6), we propose that the first layers of thio-, oxo-thio-Mo oligomers anchored onto the WSe₂ substrate serve to direct the formation of the subsequent layers by hetero-nucleation (or heterogeneous growth). The observed increase of S/Mo ratio thus arises from the addition of selected oligomers displaying higher sulphide or disulphide groups density or higher S/Mo ratio such as (MoS₂)²⁻. Lastly, these various interactions and reticulation are probably enhanced during the final drying stage improving the film consolidation.

Because our film forming process involves water-soluble Mo-complexes, a crucial advantage arises from the conversion of the Mo oxo-thio-oligomers into an amorphous solid film is its durability. This is illustrated on Fig. 5b showing a chrono-amperometric curve recorded under chopped light on a dip coated WSe₂ electrode. Moreover, XPS spectra recorded on films before and after the HER do not reveal significant change in S/Mo or tₚₑ values. In accordance with previous works [15,16], our results demonstrate the stability of the thio-Mo-complexes during the HER in the acidic electrolyte. Note that these first results are achieved on Mo complexes deposited on the 2D materials and we anticipate that this long term stability could be greatly improved by subsequent encapsulation in Nafion [16].

To provide insights into the performance enhancement resulting from the thio-, oxo-thio-Mo complexes film deposition, we further assess the PEC performances of the catalyst film and examine its electronic behaviour. Electrochemical Impedance Spectroscopy (EIS) measurements were performed on coated and non-coated WSe₂ photo-electrodes using a MoSy catalyst film to provide an experimental evidence of the decrease of the charge transfer resistance resulting from the co-catalyst film deposition. Typical Nyquist plots are presented in Fig. 59a and 59b, respectively for bare and for coated WSe₂ electrodes under illumination at different potentials. One can notice that no important variation for the bare electrode oppositely to the coated WSe₂ film is observed, for which a decrease of the low frequency loop occurs with electrode polarisation. As a result, it is highly likely that the low frequency electrode impedance is driven by the charge transfer resistance [51] for the coated sample while charge recombination is the limiting step for the bare electrode. Because the different time constants were better highlighted in admittance plots compared to the Nyquist representations, Fig. 59c and d report the admittance plots recorded on bare and coated WSe₂ electrodes under illumination at different potentials. The admittance plots can be break down into three semi-
circles. The high frequency one (right side of the plot) exhibits a constant diameter over polarisation, the two others (from right to left) show variable diameters for the coated samples but not for the bare one. Indeed, two loops are clearly visible particularly at low polarisation, –beyond +0 mV vs NHE– until only one prevails at higher polarisation.

To get a better insight into the charge process within the different electrodes, an equivalent circuit is proposed taking into account the different time constants. This equivalent circuit includes a string of three \( Z_2 \) (see details in Fig. S9e, f) in series with series resistance \( R_0 \), the latter standing for the electrolyte resistance. Each \( Z_2 \) has been ascribed to different processes: \( Z_{acc}(1) \) for the so called bulk impedance, \( Z_{arc}(2) \) for the impedance relative to the surface states [51] or recombination process and \( Z_{int}(3) \) for the interface impedance (charge transfer resistance together with the interface capacitance). In Tables S9-1 and S9-2 are reported the different values obtained. One can notice that for the coated sample beyond 0 mV NHE, only one time constant is needed to fit the curves confirming what was observed in the respective admittance plots. The interface capacitance values extracted for the bare and coated WSe\(_2\) electrodes and reported in Fig. 6a show no significant changes. Because these capacitance values give a good estimation of the electrochemical surface area, the nearly constant values of the interface capacitance determined for both electrodes indicate that the impedance of the interface is mainly driven by charge transfer and recombination resistances. From these data two kinds of resistances can be extracted. The first one is ascribed to recombination processes, the other to charge transfer (Fig. 6b). As reported in the Supp. Info., our results were best fitted by a series equivalent circuit meaning that the limiting step is dictated by the higher resistance. In this model, the higher the charge carriers’ recombination is, the higher the recombination resistance \( R_{rec} \) is. As it can be noted, the coated WSe\(_2\) electrodes display always lower overall resistance values – the sum of the two resistances – compared to those determined from the bare WSe\(_2\) electrodes. Having a closer look to the respective resistances, one can notice the \( R_{rec} \) of the coated WSe\(_2\) is always one order of magnitude lower than the charge transfer resistance signifying that this latter determines the electrode kinetic. Concerning the bare WSe\(_2\) electrode, the two resistance values are closer. This could explain the lower sensitivity of this electrode’s impediment to polarisation as the recombination plays a non-negligible role in the whole electrode process. As a result, all our observations suggest that for the bare electrode the limiting step is charge recombination while predominance of charge transfer for the coated electrode strongly indicates an efficient surface defect passivation by the co-catalyst film.

To better ascertain the functionalities displayed by the various layers building up the photocathode, the electronic properties of the co-catalyst film were next assessed. The semiconducting property of the catalyst film was revealed from UV–vis absorption spectra (Fig. S10) recorded on co-catalyst film deposited on glass substrates and annealed at 110 °C. The direct optical transition of the co-catalyst film was demonstrated from the straight line observed by plotting \((ahv)^2\) against photon energy (hv) (Fig. 6c) from which a band gap of 1.80 eV can be extrapolated. Moreover, properties of the semiconducting catalyst electrolyte interface were investigated in 0.1 M Na\(_2\)SO\(_4\), pH 7, using a co-catalyst film deposited on a FTO-Glass substrate. The Mott-Schottky plots (Fig. 6d) determined from the capacitance measurements revealed a n-type semi-conduction, a flat band potential of +0.4 V vs NHE (pH 1.5) and a charge carrier density of \(10^{21} \text{cm}^{-3}\). From this donor density along with the flat band potential value, position of the conduction band was determined at +0.3 V vs NHE (For details, See section 3, Supp. Info.).

To construct the band energy diagram of thi-o, oxo-thio Mo complexes co-catalyst film and WSe\(_2\), we have determined the band gap of p-WSe\(_2\) films formed from our exfoliated nanoflakes (\(Eg = 1.45 \text{eV}\)). Using the previous optoelectronic properties determined for the co-

Co-catalyst film = Thio, oxo-thio-Mo complexes pH 9, S/Mo = 5. Electrolyte 0.5 M H\(_2\)SO\(_4\), pH 1. c) UV–vis absorption curve recorded on Mo complexe co-catalyst film drop casted on FTO substrate. d) Mott-Schottky plots of Mo complexe co-catalyst –FTO showing a positive slope and a flat band potential \(E_B = +0.05 \text{V vs NHE at pH 7}\). The co-catalyst film was prepared by drop casting, air evaporation and heat treated in air atmosphere at 110 °C, 10 min. Electrolyte 0.1 M Na\(_2\)SO\(_4\), pH 7. Capacitances values were extracted from the EIS measurements at 100 Hz. e) Schematic for the energy band structure of Mo complexe co-catalyst-WSe\(_2\) heterojunction. The band gap value of WSe\(_2\) was determined from transmittance-reflectance curves recorded on WSe\(_2\) nanoflakes film drop casted on a glass substrate.
catalyst film, and a conduction band energy level of $-0.45$ V vs NHE [52] for the WSe$_2$ nanoflakes film, the band energy diagram (Fig. 6e) shows that the n-MoxSy co-catalyst film displays reasonable energy level for ensuring efficient charge separation and migration of the photo-induced electrons from the p-WSe$_2$ photo-electrode to produce hydrogen.

In addition to developing a high photocatalytic activity (Table S4), the multicomponent co-catalyst film was shown to exhibit multiple advantages. The Mo complexes co-catalyst film possesses a n-type semiconduction yielding a p/n junction resulting in increased band bending [53]. More interestingly, the co-catalyst film is able to heal photo-electrodes displaying high surface defects density such as 2D WSe$_2$ nanoflakes. Faced with the multicomponent character of the co-catalyst film, respective roles of the various complexes as healing additives and catalyst were explored on model Mo thio-complexes and supported by DFT calculations.

3.5. Insights into the respective roles of Mo monomers and Mo polynuclear thio-, o xo-thio complexes as healing additives and catalysts

Fig. S11 reports typical i(v) curves recorded on films prepared by selective dip coating in Mo complexes solutions fabricated at S/Mo = 5 at various pH or impregnation time durations. Depending on their forming conditions, films displaying similar dark currents (or electro-catalytic activities) can exhibit different photocurrent densities ranging from 0.25 to 2.0 mA cm$^{-2}$. On the other hand, films exhibiting different electro-catalytic activities can display a similar photocurrent up to $\sim 2$ mA cm$^{-2}$. These non-correlated evolutions of catalytic activity and photocurrent density demonstrate that our films display a multi-component character and are composed of various Mo complexes with specific properties. These results suggest that our films do not act as simple protective layers [54,55] such as previously described ultrathin Al$_2$O$_3$ films [54]. More particularly, our films are formed from a mixture of Mo complexes displaying high catalytic activity with complexes capable to heal surface defects. Because our Mo complexes are prepared in alkaline conditions where monomers and oxo-thio-complexes are in significant proportions, it is thus crucial when designing all-aqueous Mo complexes to better evaluate the respective contributions of the thio Mo complexes ((MoS$_4$)$_2^{2-}$, (Mo$_2$S$_{12}$)$_2^{2-}$), and of the o xo-thio Mo complexes on the catalytic activity and the healing effect. The properties of WSe$_2$ electrodes coated exclusively with pure (MoS$_4$)$_2^{2-}$ prepared in DMF as previously described in the literature [16] were thus investigated in a large range of catalyst loadings (30 $< n$ nanomoles $< 500$). Large

$\text{J. Barros Barbosa, et al.}$
current densities up to 10 mA cm⁻² at −0.4 V vs NHE in the range of the best current densities recorded on films prepared from our water-soluble thi Mo complexes were achieved with pure (MoS₂)₁²⁻ high-lighting the high electro-catalytic activity displayed by this complex. Concerning its photo-catalytic properties, the photocurrents recorded on pure (MoS₂)₁²⁻ films remain significantly lower than those observed on films fabricated by dip coating from our oxo-thio Mo complexes solutions (Fig. S11b). Therefore, the higher photocurrent densities up to 2 mA cm⁻² at −0.2 V vs NHE recorded on our films highlight the healing effect of the Mo thio monomers or oxo-thio complexes compared to pure (MoS₂)₁²⁻ on the 2D WSe₂ surface defects.

To support these findings, DFT calculations of adsorption energies and catalytic activity of the various Mo complexes were performed. As previously discussed, the various molecular structures can occur either as a reticulated polymer or as isolated building blocks. Moreover, no significant evolution was observed on the Raman spectra recorded before and after acid soaking or HER cycling (Fig. S8) revealing no changes of structure or composition of the thio-, oxo-thio-Mo complexes through the HER in acidic solutions consistent with previously results reported in the literature [15,16]. From all these results concerning the film composition, as a primary screen, we have investigated the role of free-standing as well as anchored thio-, oxo-thio- Mo complexes respectively as healing additives and catalysts. More particularly, our DFT calculations were performed on thio, (MoS₂)₁²⁻, oxo-thio, (MoS₂O)₁²⁻ monomers and (MoS₂)₁²⁻, (MoS₂O)₁²⁻ dimers.

3.5.1. Catalytic activities of free-standing (MoS₂O)₁²⁻, (MoS₂)₁²⁻ and (MoS₂O)₁²⁻ complexes

More insights into the intrinsic catalytic activities of the (MoS₂)₁²⁻, (MoS₂O)₁²⁻ monomers and (MoS₂)₁²⁻, (MoS₂O)₁²⁻ dimers were gained in a first stage by gas-phase DFT calculations. This was carried out using a molecular approach (for details, see Section 2, Supp. Info.) on H absorption energies on free-standing (MoS₂)₁²⁻, (MoS₂O)₁²⁻ monomers and free-standing (MoS₂)₁²⁻, (MoS₂O)₁²⁻ dimers in their radical forms. We recall that the free Gibbs energy of H-adsorption is a good descriptor of the ability of a given compound to be active for HER, when ΔGₜₜ remains close to ±0.1 eV [36]. Unlike (MoS₂)₁²⁻ and (MoS₂O)₁²⁻ monomers, low hydrogen adsorption energies were determined on free-standing (MoS₂)₁²⁻ and (MoS₂O)₁²⁻ complexes (Fig. 7). While confirming the low hydrogen adsorption energy of the (MoS₂)₁²⁻ thio complexes reported in literature [16], these calculations highlight the ability of oxo-thio Mo complexes such as (MoS₂O)₁²⁻ to catalyse the HER. In addition, it is worthy to note that from our DFT calculations the M = O units were identified as the more active site for the HER on (MoS₂O)₁²⁻ complexes.

3.5.2. Adsorption energies of thio-, oxo-thio-Mo complexes on point defects of 2D WSe₂ materials

Fine inspection of the HRTEM images clearly reveals that defects in 2D WSe₂ nanosheets occur on the edges or are located in the basal plane due to non-stoichiometry (Fig. S12). From TEM observations, our WSe₂ nanoflakes possess average lateral dimensions of 1 μm × 1 μm and a thickness of about 5 monolayers. When assuming a defect concentration of 0.5 % in the for the HER, a simple calculation reveals an equivalent number of peripheral edge or in-plane defect sites. In addition, and as expected, preliminary DFT calculations have shown a stronger adsorption of the thi complexes on the edge sites. From these results, we have paid particular attention in our DFT calculations to point defects. Regarding point defects, best performance for the HER was achieved on films prepared from solutions containing MoS₂O²⁻, MoS₂O²⁻ monomers, (MoS₂)₁²⁻ and (MoS₂O)₁²⁻ dimers in high proportions. During the catalyst film formation, these negatively charged thio-complexes preferentially interact electrostatically in basic aqueous solution with locally charged defects of the 2D substrate. Reported defects on the 2D substrate include edges [6], large scale defects such as tears [34,56] or point defects such as Se vacancies, W vacancies [57]. Typical point defects of the WSe₂ substrate, namely Se-vacancy and W-vacancy are known to be electron acceptors [57−59] with formation energy we have determined respectively of 2.6 and 5.3 eV. Note that these vacancies always yield very small atomic reorganization with stretching of the W-Se bonds less than 0.1 Å (Fig. S13). In addition to have a considerable effect on carrier recombination, scaling of these point defects with the molecular size of the Mo complexes makes a meaningful DFT investigation focussed on point defects rather than large scale defects. The Mo complexes, (MoS₂)₁²⁻, (MoS₂O)₁²⁻ monomers, and (MoS₂)₁²⁻, (MoS₂O)₁²⁻ dimers chosen as model Mo species were put in interaction in their radical form with (i) a pristine, (ii) a single Se-vacancy and (iii) a W-vacancy WSe₂ monolayer. Table 1 summarizes the adsorption energy of Mo-complexes, defined as Eads = EMo-comp− substratEsubstr, for the model substrate presenting (or not) Se or W vacancy, where EMo-comp=substrat− Esubstr and EMo-comp stand for the total energy of the adsorbed species on the model WSe₂ substrate, for the total energy of the substrate alone and of the Mo-complex alone respectively. From the values, it appears that the Mo-complexes weakly bind with defect-free pristine WSe₂ substrate and always prefer to stack on W-vacancy (see Fig. 7 for the adsorption modes on the W-vacancy site and Fig. S14a, b for other adsorption sites). Interestingly, (MoS₂)₁²⁻, (MoS₂O)₁²⁻ monomers or polycondensed species displaying a small size such as (MoS₂O)₁²⁻ were shown to bind stronger than the (MoS₂)₁²⁻ complex to point defects of the WSe₂ substrate. Note that DFT calculations show that oxo-thio complexes are better adsorbed compared with their thi analogues on the WSe₂ substrate containing Se or W vacancies. In contrast to the disruption of S₂²⁻ bonds into active S²⁻ anions previously reported in the presence of nucleophiles favouring subsequent reactions with metal ions producing metal sulphides [60,61], the interaction between a W-vacancy and the various complexes investigated (MoOS₂)₁²⁻, (MoS₂O)₁²⁻, (MoS₂)₁²⁻ ) results in the formation of new Se−O bonds (d = 2.3 Å) as illustrated on Fig. 7a. Therefore, we propose that the passivation of the surface defects of the WSe₂ nanosheets arises from the strong adsorption of these Mo complexes onto the WSe₂ nanosheets while interacting with the Se and W vacancies. Note that the stronger adsorption displayed by Mo monomers or small size dimers such as (MoS₂O)₁²⁻ toward point defects shown from our calculations is consistent with our experimental results. This highlights the crucial role of these latter Mo complexes compared with pure (MoS₂)₁²⁻ to passivate the surface defects on 2D WSe₂.

3.5.3. Catalytic activities of thio-, oxo-thio-Mo complexes in anchored configuration

Although in our DFT calculations we exclusively consider point defects and deal with adsorption of radical vs charged Mo complexes, our calculations highlight that good catalytic performance will mainly arise from dimers such as (MoS₂O)₁²⁻ or (MoS₂)₁²⁻ preferably in a free standing regime or anchored in a low adsorption regime, i.e. on point defect-free WSe₂ substrates (Fig. 7c). In contrast, (MoS₂)₁²⁻, (MoS₂O)₁²⁻, (MoS₂)₁²⁻ complexes strongly adsorbed on W-vacancy containing WSe₂ monolayers show A⁰⁺H values far from the optimum of the Volcano curve [34] indicating a low activity for the HER. Thus, | Table 1 |
| Adsorption energies (in eV) of various Mo-complexes in their radical forms, for three distinct substrate configurations of the WSe₂ monolayer. |
| Adsorption energies onto WSe₂ (in eV) | Free – defect Pristine substrate | Se-Vacancy containing WSe₂ substrate | W-vacancy containing WSe₂ substrate |
| (MoS₂)₁²⁻ | +0.09 | −0.15 | −1.75 |
| (MoS₃O)₁²⁻ | −0.59 | −0.97 | 2.64 |
| (MoS₃S)₁²⁻ | −0.09 | −0.11 | −0.29 |
| (MoS₂O)₁²⁻ | 0.13 | −0.19 | 0.99 |

J. Barros Barbosa, et al.
DFT calculations showed that our water-soluble Mo-oxo-thio complexes distributions are composed of three various classes of molecular species: i) Mo monomers possessing a low catalytic activity in its free-standing configuration but displaying high adsorption energy onto 2D WSe₂, ii) \( \text{Mo}_{2}S_{2}S_{2}^{2−} \) dimer displaying high catalytic activity for the HER but with relatively low affinity for the 2D WSe₂ substrate. iii) \( \text{MoS}_{2}O_{4}^{3−} \) oxo thio monomer displaying strong adsorption towards the WSe₂ substrates and reasonable catalytic activity in its anchored configuration. These Mo oxo-thio complexes distributions are capable both of passivating surface defects and displaying catalytic configuration can therefore be described as healing catalysts.

Consistent with our experimental results, we propose that the observed high HER performance arises from oxo-thio Mo complexes films probably composed of Mo monomers, dimers and trimers which are present in addition to a reticulated polymer both in free-standing and anchored configurations. Low adsorption and high adsorption modes of the Mo complexes should coexist for the anchored configurations depending of the point defects local concentration. We have demonstrated that the optimum structure of the catalyst film including free-standing and strongly adsorbed complexes providing respectively catalytic and healing properties can be successfully achieved from well-defined aquo-oxo-thio Mo complexes distributions through selective dip coating. Nevertheless, deep insights into the film structure describing respective proportions of healing and catalytic additives as well as the detailed conformation of the polymer and the complexes inside the film remain to be elucidated.

3.6. Implications for the hydrogen evolution reaction mechanism

Different scenarios are proposed to date for the Hydrogen Evolution Reaction catalytic cycles on Mo thiophosphate complexes especially in the presence of \( M = O \) moiety [28]. More particularly, the HER catalytic cycle reported in the case of high performance amorphous MoSx films prepared by electrodeposition involves unsaturated Mo(IV) and Mo(V) sites with transient formation of the \( M = O \) moiety during the catalytic cycle. In another study concerning the same material, the catalytic cycle is shown to involve the \( S_{2}^{2−} \rightarrow S^{2−} \) redox reaction [28]. In recent works [27,28] dealing on \( \text{MoO}S_{2}(2,2′-\text{bipyridine}) \) as oxo thio Mo model molecule, a \( H_{2} \) evolution catalytic cycle involving a hardly attached \( M = O \) moiety which functions as a proton relay is proposed for the HER reaction. In this catalytic mechanism, the \( S_{2}^{2−} \) anion represents the redox centre associated with a Mo(V) site. Note that these various catalytic cycles were proposed for the hydrogen electrocatalytic evolution reaction. A crucial difference between the photocatalytic vs electrocatalytic electrochemical water decomposition, is the shift of potential arising from the solar energy harvesting. This shift towards lesser cathodic potentials does not favour the Mo(V) → Mo(IV) reduction which is reported to occur at \(-0.3 \text{ V} / \text{NHE} \) in slightly acid medium [32]. Because hydrogen evolution in our photocatalytic experiments does not require any cathodic pre-activation nor the high cathodic potentials for the Mo(V) → Mo(IV) reduction, we believe that our photocatalytic cycle for the HER implies terminal \( S_{2}^{2−} \).

This work should pave the way to further design a larger range of environmentally-friendly, aqueous-stable, multicomponent [62], catalytically active passivation layers made of thi-o, oxo-thio- Mo complexes. Besides developing catalytic activity and healing property, these multicomponent films with a n-type semi-conduction along with its suitable optoelectronic properties were shown to improve charge separation and migration for the HER thus providing an example of engineering of multicomponent, passivation layer displaying multiple properties.

While this work was focused on 2D WSe₂ materials which possess a considerable surface defect density, use of these highly interactive, oxo-thio, molecular complexes could be extended to passivate surface defects of a larger range of high surface area photo-electrodes like p-WS₂ or p-MoS₂ for the HER. Further developments can also be anticipated with the design of M doped- Mo-oxo-thio-complexes [63], where M = metallic cation [26], rare earth elements [64], especially to achieve lower cathodic HER onset potentials or higher catalytic activity in neutral aqueous electrolytes. Indeed, because of their ability to absorb a significant fraction of the solar spectrum using ultrathin films, 2D TMDC materials (p-MoS₂, p-WS₂, p-WSe₂) displaying various band gaps and onset potentials for HER [48] represent ideal photocathode candidates for the engineering of photo-electro-chemical tandem cells [65].

4. Conclusions

Co-catalyst films composed of Mo thio- and oxo-thio- complexes which spontaneously form in \( \text{H}_{2}\text{O} \) in well-defined S/Mo ratio and pH conditions, are proposed as HER catalysts. Photocatalytic decomposition of water was successfully achieved on photocathodes prepared from exfoliated 2D-WSe₂ and activated by highly interacting complexes selected from Mo oxo-thio complexes distributions via a selective dip coating film forming process. The best photocatalytic results were observed on 2D p-WSe₂ photo-electrodes after deposition of Mo monomers, \( \text{(Mo}_{2}S_{2}S_{2})^{2−}, \text{(Mo}_{2}S_{4}O_{4})^{2−} \) and \( \text{(Mo}_{2}S_{4}O_{4})^{2−} \) with photocurrents up to \( 2.0 \text{ mA cm}^{2} \) at \(-0.2 \text{ V} / \text{NHE} \). Compared to Pt-Cu catalysts, the higher photocurrents observed after deposition of the thio- and oxo-thio- Mo complexes, without the use of any passivating additive on the 2D photo-electrodes, reveal an additional healing effect arising from the oxo-thio Mo complexes films. The healing property of the co-catalyst film was experimentally demonstrated by photoluminescence and electrochemical impedance spectroscopy. Insights into adsorption energies and final conformations of the thio and oxo-thio complexes on the 2D photo-electrodes are given from DFT calculations. DFT results highlight the crucial healing role of oxo-thio Mo monomers and to a lesser extent, of smaller oxo-thio- Mo dimers. These films also provide an example of the engineering of a multicomponent passivation layer displaying multiple properties including healing, better charge separation and migration and catalytic activity. The strategy illustrated here on 2D materials and relying on strongly adsorbed molecular species could be extended to other large surface area photo-electrode materials displaying high concentrations of surface defects.

Author contributions
