Abstract. We review the longterm confusion which has existed over the nature of flaring in the brightest class of low mass X-ray binary: the Z-track sources, specifically in the Cygnus X-2 sub-group. Intensity reductions in the lightcurve produce a branch in colour-colour diagrams similar to that of real flares in the Sco X-1 like group, and the nature of this branch was not clear. However, based on observations of Cygnus X-2 in which this dipping/flaring occurred it was proposed that the mass accretion rate in Z-track sources in general increases monotonically along the Z-track towards the Flaring Branch, a standard assumption widely held. It was also suggested that the Cygnus X-2 group have high inclination. Based on recent multi-wavelength observations of Cygnus X-2 we resolve these issues, showing by spectral analysis that the Dipping Branch consists of absorption events in the outer disk, unrelated to the occasional real flaring in the source. Thus motivation for $\dot{M}$ increasing along the Z from Horizontal - Normal to Flaring Branch is removed, as is the idea that high inclination distinguishes the Cygnus X-2 group. Finally, the observations provide further evidence for the extended nature of the Accretion Disk Corona (ADC), and the correct modelling of the ADC Comptonized emission is crucial to the interpretation of low mass X-ray binary data.

Key words. Physical data and processes: accretion: accretion disks — stars: neutron: individual: Sco X-1, GX 349+2, GX 17+2, Cyg X-2, GX 5-1, GX 340+0 — X-rays: binaries

1. Introduction
The Z-track sources are the most luminous low mass X-ray binaries emitting at and above the Eddington limit. Spectral variability presented in a hardness-intensity or colour-colour diagram shows three distinctive tracks having a Z-shape known as the Normal (NB), Horizontal (HB) and Flaring (FB) Branch (Hasinger & van der Klis 1989). This suggests major physical differences at the inner disk and the neutron star. There are six main Galactic Z-track sources known: Cyg X-2, GX 340+0, GX 5-1, Sco X-1, GX 17+2, GX 349+2) and also the transient source (XTE J1701-462) (Lin et al. 2009). Based on the shapes, hardness-intensity diagrams of the Z-track sources are divided into two groups: the Cyg-like sources with a short Flaring Branch and a distinct Horizontal Branch, and the Sco-like sources with a strong Flaring Branch and a weak Horizontal Branch.
The nature of the three states and the cause of the differences between the two sub-groups have not been understood.

In this paper we will concentrate on the longterm confusion between absorption dipping and flaring found in the Cygnus X-2 like Z-track sources. Dipping in Cygnus X-2 was first detected by Bonnet-Bidaud & van der Klis (1982). In the pioneering work of Hasinger and co-workers the spectral and timing properties of the Z-track sources were revealed. Hasinger & van der Klis (1989) showed that Cyg X-2 and GX 340+0 exhibited full Z-tracks in colour-colour diagrams with three branches. However, the Flaring Branch, i.e. the lower branch on the Z as seen in other Z-track sources, was associated with intensity decreases. Hasinger et al. (1990) in a multi-wavelength campaign on Cygnus X-2 using Ginga similarly found that the there were intensity decreases on the FB that “could be mistaken for absorption dips”. Kuulkers & van der Klis (1995) argued that in Cyg X-2 and GX 340+0 the FB in colour-colour representations corresponds to X-ray dipping (while in the Sco-like source the FB corresponds to strong flaring increases of intensity). Hence they suggested that the Cyg-like sources have high inclination angle distinguishing them from the Sco-like sources and proposed a model for the Cyg-like Sco-like differences involving absorption or scattering in the inner disk. Previously, there has been a lack of reliable spectral fitting of the Dipping Branch to establish its nature. In the present work, we carry out systematic spectral fitting of the Dipping Branch using data from our 2009 multi-wavelength campaign (Bałucińska, M., Schulz, N., Wilms, J., Gibiec, A., Hanke, M., Spencer, R. E., Rushton, A., Church, M. J., 2011, A&A, 530, A102) and show that the dip events are unrelated to flaring. Thus there is now no motivation for an explanation of the Z-track sources based on inclination.

In the 1988 multi-wavelength campaign it was argued that the UV flux increased from HB - NB - FB (Vrtilek et al. 1990). As the UV flux was regarded as a good measure of a mass accretion rate \( M \), it was proposed that \( M \) increases monotonically from HB - NB - FB, i.e. suggesting that the physical changes between the three states in the Z-track sources in general are driven by mass accretion rate (Hasinger et al. 1990). This became adopted generally as a standard model; however as realized at the time by Hasinger and co-workers the decrease of X-ray intensity on the NB between Hard and Soft Apex runs counter to simple expectations. Moreover, it is clear from the present work that the Flaring Branch in Cygnus X-2 in colour-colour diagrams actually consists of absorption dips while real flaring data is only occasionally seen.

![Fig. 1. A variety of Z-track effects in the Cyg-like sources shown in hardness-intensity, including intensity reductions in dipping.](image-url)

**2. The Dipping/Flaring confusion**

It has been known for some time that the Cyg-like sources show extra tracks in hardness-intensity addition to the three main branches. In Fig. 1, four examples are shown using Rossi-XTE data. Firstly, we show a normal Z-track for Cygnus X-2 (top left panel) with HB, NB and FB. In fact, based on examining all of the data in the RXTE archive, it is found that a normal Flaring Branch occurs rarely in this
source. The next two panels also show observations of Cygnus X-2 not executing a full Z-track, but displaying definite intensity reductions from about the location of the soft apex between NB and FB. Such decreases are seen in many observations and are discussed further below. Finally, in the lower panel, a Z-track is shown for GX 5-1 with a fourth branch consisting of intensity reductions from the peak of flaring. Similar behaviour is seen in GX 340+0 clearly also suggestive of absorption.

Fig. 2. Hardness-intensity and colour-colour diagrams of Rossi-XTE data showing intensity decreases (dips) in Cyg X-2.

In Fig. 2, we show intensity decreases in RXTE archival data on Cygnus X-2 in the two forms: hardness-intensity and colour-colour. While it is clear from hardness-intensity that intensity decreases take place visible as dips in the lightcurve, when plotted in colour-colour these events appear to look like flaring, demonstrating the nature of the confusion.

3. Resolving the dipping controversy in Cygnus X-2: the multi-wavelength campaign of 2009

We observed Cygnus X-2 in a multi-wavelength campaign in 2009, lasting 24 hours from May 12, 9:30 UT to May 13, 9:20 UT using Newton XMM and Chandra simultaneously and the European VLBI network at 5 GHz (Bałucińska-Church et al. 2011). In addition UV data in the band 2500 - 4000 Å were provided by the XMM Optical Monitor. X-ray data were obtained from the XMM EPIC-pn camera in the band 0.6 - 12 keV using burst mode because of the brightness of the source and the RGS instrument providing high resolution spectra in wavelengths 20.7-37.6 Å. The Chandra MEG and HEG and gratings provided high resolution spectra at wavelengths greater than ~ 13 Å (0.5 - 8.0 keV).

Lightcurves of the observation in the X-ray instruments: the EPIC-pn, the RGS and the Chandra MEG and HEG are shown in Fig. 3 together with the Optical Monitor lightcurve. In the top panel, the second part of the observation covered by radio observations is indicated by a bar; the radio flux was less than 150 microJy/beam, i.e. the source was radio quiet (Rushton et al. 2009) consistent with the source’s position on the Z-track (below) away from the Hard Apex. The X-ray data exhibit extensive dipping as seen in Fig. 3. In Fig. 4 we show a hardness ratio as a function of time for the EPIC-pn defined as the ratio of counts per second in the band 4.5 - 8.0 keV to that in 0.5 - 2.5 keV. A clear increase in hardness ratio is seen at the intensity dips suggestive of photoelectric absorption. However, remarkably, hardness ratios based on an energy band below 2 keV in EPIC and a similar ratio using RGS data showed no change in hardness in dipping as will be discussed later.

From these data, the evolution of Cygnus X-2 in hardness-intensity was derived as shown in Fig. 5. The source did not execute movement along the Z-track but remained at a stable position throughout the 24 hours of observation. Spectral fitting (below) reveals parameter values expected at or close to the Soft Apex. The excursions to lower intensity were found to correspond to dips in the light curve.

3.1. Continuum spectral fitting

Non-dip and dip spectra were fitted using the Extended Accretion Disc Corona model (Church & Bałucińska-Church 2004) as justified by the now very strong evidence for an extended ADC (Bałucińska-Church et al. 2011). The emission is dominated as in LMXB in general by Comptonized emission and this model
recognizes that for an ADC extending to large radial distances, the seed photons will consist of thermal emission from the accretion disk. Thus a model was used consisting of blackbody emission from the neutron star plus a cut-off power law Comptonized emission.

Fitting non-dip, intermediate and deep dip spectra showed that dipping consisted of absorption of partially covered Comptonized emission. However, remarkably, emission from the neutron star was not absorbed at all, contrasting radically with dipping in the dipping class of LMXB (e.g. Church et al. 1997). Best fit models and unfolded data are shown in Fig. 6: The decrease of the Comptonization due to photoelectric absorption is clear, and of an emission feature at \( \sim 1 \) keV. However, the lack of change of the broad neutron star blackbody peaking at 3 keV is also very clear, showing that the neutron star is not overlapped by absorber.

3.2. The grating spectra

In Fig. 7 we show the XMM RGS grating spectrum of non-dip data revealing a strong absorp-

Fig. 8. Chandra high resolution non-dip (upper panel) and dip spectrum (lower panel) of Cyg X-2 in the vicinity of the Ne K edge.

The Chandra HEGTS spectra reveal a number of absorption edges of Mg K, Ne K, Fe L and O K at 9.48 Å (1308 eV), 14.29 Å (867 eV), 17.51 Å (708 eV) and 22.89 Å (542 eV). Fig. 8 shows non-dip data (upper panel) and dip data (lower panel). Remarkably, investigation of the edges notably the Ne K edge in the Chandra MEG and the oxygen edge in the RGS showed the optical depth did not change in dipping. This can be explained in terms of a partial covering model.

3.3. Model for dipping in Cygnus X-2

Dipping is unusual in this source in several respects: the neutron star emission is not absorbed; the optical depth in the edges does not increase in dipping and the hardness ratios defined below 2 keV do not change in dipping (Fig. 4). These features can be explained as follows. The major effect in dipping is a gradual part removal of the Comptonized emission. Gradual removal is well-modelled by partial covering and proves the extended nature of the ADC emission. Given the high inclination of the source of 62° it is clear that the absorber will be structure in the outer accretion disk. The spectra are well described with this model:
in intermediate dipping with a covering factor of 18% and column density $N_{\text{H}} = 13 \times 10^{22}$ atom cm$^{-2}$ and in deep dipping with a covering factor of 42% and $N_{\text{H}} = 45 \times 10^{22}$ atom cm$^{-2}$. The contributions of uncovered and covered emission to the continuum in deep dipping are shown in Fig. 9 using the continuum fit results (neglecting lines and edges). The neutron star is not overlapped by absorber, totally different from the LMXB dipping sources (e.g. XB 1916-053, Church et al. 1997) where the neutron star is always absorbed. However, this can be explained in terms of the inclination not being quite so high as in the dipping LMXB; thus the envelope of the absorber in the outer disk covers a fraction of the ADC but misses the neutron star. Because of the high column densities in deep dipping, covered emission is totally removed below $\sim 4$ keV. Thus the hardness ratios define below 2 keV do not contain covered, only uncovered emission and so do not change in dipping. Similarly, the remarkable result that the grating data show no increase of optical depth in dipping is due to the fact that only uncovered emission is seen in dipping. Thus the gratings reveal the decrease of continuum intensity but cannot see any of the absorbed emission which would have higher optical depth.

### 3.4. Dependence of dipping on orbital phase

The multi-wavelength observation covered orbital phase of Cyg X-2 between 0.32 and 0.42. In the dipping LMXB dipping is normally confined to phase $\sim 0.75$ corresponding to the bulge in the outer disk. Clearly in the present data absorption takes place on the opposite side of the disk. To investigate further we have derived orbital phases of dipping for all observations of Cygnus X-2 containing dipping in the RXTE archive. Examination of all the RXTE ASM data in the archive as shown in Fig. 10 revealed that dipping is very common in this source, i.e. in almost all observations and using pointed data have derived the distribution of dipping with orbital phase as shown in Fig. 11. In this figure, the main peak of the distribution occurs at phase $\sim 0.75$ indicative of absorption in the bulge in the outer disk where the accretion stream impacts. However, dipping takes place at all orbital phases suggesting structure around the accretion disk rim. Thus, in conclusion there is no doubt that the Dipping Branch seen in the hardness-intensity diagrams of Cygnus X-2 consists of photoelectric absorption and is unrelated to flaring.

### 4. Dipping in GX 5-1 and GX 340+0

The confusion between dipping and flaring mainly related to the source Cygnus X-2. However, in Fig. 1 we showed a Z-track in hardness-intensity for the Cyg X-2 like source GX 5-1 in which a 4th track is seen of decreasing intensity attached to the end of the Flaring Branch. The source GX 340+0 displays a similar 4th track. It might be supposed that these 4th tracks are related to absorption because of the intensity decreases and so are clearly relevant to the dipping/flaring confusion, so this effect is addressed here.

We have carried out spectral fitting of the evolution along the Z-track including the 4th track (Church et al. 2010). This showed that there was no trace of absorption on the 4th track. It was significant that spectral parameters such as the neutron star blackbody temperature $kT$ and blackbody radius $R_{\text{BB}}$ did not ex-
hibit change of behaviour when moving from the Flaring Branch to the 4th Branch, but exhibited the same continuous smooth variations on both branches indicating no marked physical change. However, the luminosity of the dominant ADC Comptonized emission, essentially constant on the FB, exhibited a decrease on the 4th Branch as also seen on the NB between the Hard and Soft Apex. This strongly suggests a decrease of mass accretion rate and shows that the 4th Branch consists of a continuation of $\dot{M}$ decrease which was already taking place as the source moved down the Normal Branch to the Soft Apex at which point flaring began, identified as unstable nuclear burning (Church et al. 2006). The 4th Branch thus consists of the continuation of decrease of $\dot{M}$ during the flaring and the significant result is that it is unconnected with absorption.

5. Conclusions

Based on a multi-wavelength campaign on Cygnus X-2 we have resolved the dipping/flaring confusion in this source. In these observations, strong dipping took place and spectral analysis showed this to consist of photoelectric absorption in which $\sim 40\%$ of the extended Comptonized emission of the ADC was overlapped by absorber in the outer disk; however, the neutron star emission was not absorbed indicating that it was not overlapped by absorber. The grating spectrometers also showed the dips as continuum decreases but without increase of optical depth in dipping as all emission below 4 keV was removed.

The original argument that dip data displayed in a colour-colour diagram appeared very similar to a Flaring Branch led to the idea that the mass accretion rate increased on this branch and that this increased monotonically around the Z-track in the direction HB - NB - FB. Moreover the detection of dipping in Cyg X-2 and GX 340+0 led to the idea that this sub-group of Z-track sources differed from the Sco X-1 like sources by having high inclination. While dipping clearly takes place in Cygnus X-2 having high inclination, we now see that apparent dipping in GX 5-1 and
GX 340+0 probably relates to the 4th Branch and is not absorption, so the motivation for inclination distinguishing Cyg-like and Sco-like sources no longer remains. Similarly, the motivation for $M$ increasing in the direction HB-NB-FB does not remain.

We have previously suggested a physical model for the Cyg-like sources (Bałucińska-Church et al. 2010) based on increase of mass accretion on the NB and unstable nuclear burning on the FB. We have also recently proposed an explanation of the Sco-like source behaviour in Sco X-1, GX 349+2 and GX 17+2 (Church & Bałucińska-Church 2011: these Proceedings). In this explanation, the sources are dominated by almost non-stop flaring which releases energy on the neutron star leading to much higher neutron star temperatures: the main spectral difference.

In the other Cyg-like sources GX 340+0 and GX 5-1, the 4th Branch in which the X-ray intensity decreases from the end of the Flaring Branch has been shown to be unrelated to absorption dipping (Church et al. 2010).

Finally, the investigation of dipping in Cygnus X-2 provides additional proof of the extended nature of the Comptonizing ADC, adding to the proof provided by the technique of dip ingress timing (Church & Bałucińska-Church 2004) and by the Doppler widths of highly ionized emission lines (Schulz et al. 2009). The gradual removal of this emission as clearly seen in the development of dipping, and formalized by fitting of a partial covering model with increasing covering fraction, would not be possible if the Comptonizing region was not extended. Thus the conception of the Comptonizing region widely held by parts of the community as a small, hot central region (by definition a point source given a size of 1000 km or less) is no longer tenable.
