(Dated: December 2, 2011)

We investigate the quantum heat exchange between a nanojunction and a many-body or electromagnetic environment far from equilibrium. It is shown that the two-temperature energy emission-absorption mechanism gives rise to a giant heat flow between the junction and the environment. We obtain analytical results for the heat flow in an idealized high impedance environment and perform numerical calculations for the general case of interacting electrons and discuss the giant freezing and heating effects in the junction under typical experimental conditions.

Quantum dynamics of tunnel nanojunctions is governed by underlying relaxation mechanisms and nonequilibrium effects since even small currents drive a nanojunction well out of equilibrium. At low temperatures the direct energy transfer to the phonon bath becomes inefficient and relaxation is dominated by the energy exchange between the tunneling electrons and electromagnetic environment and/or to many-body excitations in the electrodes (hereafter we will refer to both mechanisms as relaxation via the environment). In this Letter we calculate the heat flow between the tunneling electrons and the environment, which control the junction dynamics, using a non-perturbative technique based on quantum kinetic equations taking into account far from equilibrium effects. We show, in particular, that a regime exists in which the interaction with the environment gives rise to a giant cooling of the nanojunction.

The energy exchange between tunneling electrons and the environment is determined by the emission of environment modes with temperature equal to that of electrons, $T_e$, and the absorption of environment excitations carrying the temperature of the thermal bath, $T_{\text{env}}$. Moreover, not only temperatures, but also the distributions of emitted and absorbed environment modes may appear essentially different in the far from equilibrium regime $T_e \gg V > T_{\text{env}} \simeq T_{\text{leads}}$, where $V$ is the voltage across the junction. Our main finding is that this two-temperature emission-absorption mechanism gives rise to a giant heat flow between the junction and the environment (see inset in Fig. 1).

In the case of a resistive environment [electromagnetic fluctuations in a cold (hot) resistor shunting the tunnel junction], the heat flow is $Q \simeq T_e R_T C \ln(R_T C/\tau_e) k_B (T_e - T_{\text{env}})/R_T C$, with comparable temperatures $|T_e - T_{\text{env}}| \ll T_e + T_{\text{env}}$. Here $R_T$ and $C$ are the ohmic resistance and capacitance of the junction, respectively, and $\tau_e$ is the electron energy relaxation time, $\tau_e \ll 1/T_e \ll R_T C$. This result well exceeds the flow in the quasi-equilibrium approximation $Q \approx k_B (T_e - T_{\text{env}})/R_T C$, where the emitted and absorbed modes have the same temperature. The large factor $T_e R_T C \ln(R_T C/\tau_e) \gg 1$ by which the two results differ, reflects the elevated effective number of environment excitations emitted by charges tunneling through the nanojunction in the out of equilibrium regime, see Fig. 1.

![Fig. 1.](image)

**Model.** — The rate of the heat flow between the tunnel junction and the environment is given by

$$Q = \int_0^\infty \varepsilon \{ n_e p(\varepsilon) - [1 + n_e] p(-\varepsilon) \} p(\varepsilon) d\varepsilon, \quad (1)$$

where $P(\pm \varepsilon)$ is the probability density for the tunneling charge-carrier to lose [gain] the energy $\varepsilon$ to [from] the environment. The distribution function $n_e$ in Eq. (1) can be interpreted as the distribution function of electron-hole pairs that appear at the junction interface just after the tunneling process: the hole in the source lead and the electron in the drain, Fig. 2a). If the distribution functions at the electrodes are Fermi functions with equal temperatures $T_e$, then $n_e = \{(\varepsilon - V) N_B(\varepsilon - V, T_e) + (\varepsilon + V) N_B(\varepsilon + V, T_e)\}/2\varepsilon$, with $N_B(\varepsilon \pm V, T_e)$ being the
equilibrium Bose distribution function. For this case the effective temperature of the nanojunction is defined as

$$T_{\text{eff}}(V,T_e) = \lim_{\varepsilon \to 0} n_{\varepsilon}(V,T_e) = \frac{V}{2} \coth \frac{V}{2T_e}. \quad (2)$$

At low applied voltages, $V \ll T_e$, the effective temperature of the junction $T_{\text{eff}}$ coincides with the temperature of the leads, $T_{\text{eff}} \approx T_e$. In the opposite case of high voltages, $V \gg T_e$, we obtain $T_{\text{eff}} \approx V/2$. The function $p(\varepsilon)$ in Eq. (1) is the weight function for a junction between two normal metals, Fig. 4, and can be calculated for any choice of the electron distribution function in the leads, resulting in $p(\varepsilon) = 4e/R_T$.

Heat flow.— To calculate $\dot{Q}$ one has to specify the probability density, which can be written in a form $P(\varepsilon) = \int_{-\infty}^\infty dt \exp[J(t) + it\tau]$, where the function $\exp[J(t)]$ reflects the fact that tunneling electrons acquire random phases due to interaction with the Bosonic environment, represented by a set of oscillators with non-equilibrium distribution of modes, $N_\omega$. The quasi-equilibrium situation where the distribution functions of the environment modes are Bose distributions parametrised by equilibrium temperatures was discussed in Ref. 2. In general far from equilibrium, $J(t)$ is [3]:

$$J(t) = 2 \int_{\tau_e^{-1}}^\infty \frac{d\omega}{\omega} \rho(\omega) \left[ N^{(\text{in})}_\omega e^{i\omega t} + (1 + N^{(\text{out})}_\omega)e^{-i\omega t} - B_\omega \right]. \quad (3)$$

The mode distribution, $N_\omega$, is defined by a kinetic equation with scattering integral describing the energy exchange between environment modes and tunneling electrons. The terms proportional to $N^{(\text{in})}_\omega$ and $1+N^{(\text{out})}_\omega$ correspond to the absorbed and emitted environment excitations, respectively. The combination $B_\omega = 1 + N^{(\text{out})}_\omega + N^{(\text{in})}_\omega$ is the kernel of the time-independent contribution to $J(t)$ describing the elastic interaction of the tunneling electrons with the environment modes. In equilibrium $N_\omega$ reduces to the Bose-function and the functional $P(\omega)$ recovers the result of Ref. 2. In Eq. 4, the energy relaxation time $\tau_e$ determines the low energy cut-off, since the electrons start to equilibrate on larger time scales, i.e. the non-equilibrium description does not hold any more. The spectral function $\rho(\omega)$ is the probability of the electron–environment interaction and characterizes the particular system under consideration.

To estimate the magnitude of the heat flow $\dot{Q}$ we first expand the distribution function $P(\varepsilon)$ in Eq. (1), in the first order in $\rho(\varepsilon)$:

$$\dot{Q}^{(1)} = \frac{4}{R_T} \int_{\tau_e^{-1}}^\infty \frac{d\varepsilon}{2\pi} \varepsilon \rho(\varepsilon) \left\{ n_{\varepsilon}(1 + N^{(\text{out})}_\varepsilon) - (1 + n_{\varepsilon})N^{(\text{in})}_\varepsilon \right\}. \quad (4)$$

The expression in Eq. (4) becomes zero if $n_{\varepsilon} = N^{(\text{in})}_\varepsilon = N^{(\text{out})}_\varepsilon$. If the distribution functions are not equal to each other, we can expand $\dot{Q}^{(1)}$ with respect to their difference. We consider the case where the voltage bias at the nanojunction is zero but the temperatures of electrons at the leads and those that comprise the environment are slightly different, $T_e = T + \delta T/2$ and $T_{\text{env}} = T - \delta T/2$. Thus, $n_{\varepsilon} = n_{\varepsilon}(T + \delta T/2)$, $N^{(\text{in})}_\varepsilon = n_{\varepsilon}(T - \delta T/2)$, $N^{(\text{out})}_\varepsilon = n_{\varepsilon}(T + \delta T/2)$, where $n_{\varepsilon}$ is the Bose distribution function. Using Eq. (1) in the first order in small parameter $\delta T/T \ll 1$ we find

$$\dot{Q}^{(1)}_\theta \approx \delta T \frac{4}{R_T} \int_{\tau_e^{-1}}^\infty \frac{d\varepsilon}{2\pi} \varepsilon \rho(\varepsilon) n_{\varepsilon}'(T)(1 + \theta n_{\varepsilon}(T)), \quad (5)$$

where $n_{\varepsilon}'(T) = dn_{\varepsilon}(T)/d\varepsilon$. The index $\theta$ is 0 for the quasi-equilibrium situation when the temperatures of emitted and absorbed environment excitations are equal and 1 for the non-equilibrium case (the index 1 is skipped throughout this Letter). Since $n_{\varepsilon}(T)$ in Eq. (3) is always positive, the following inequality is valid $|\dot{Q}_{\theta}^{(1)}| < |\dot{Q}^{(1)}|$, where $\dot{Q}_{\theta}^{(1)}$ and $\dot{Q}^{(1)}$ refer to the heat flux in quasi-equilibrium and in non-equilibrium cases, respectively. The interaction function $\rho(\varepsilon)$ in Eq. (3) quickly decays at frequencies larger than some characteristic frequency $\omega_{\text{max}}$. For temperatures $T > \omega_{\text{max}}$ (quantum regime) we can approximate $n_{\varepsilon}(T) \approx T/\varepsilon \gg 1$ and find

$$\frac{|\dot{Q}_{\theta}^{(1)}|}{|\dot{Q}^{(1)}|} \approx \frac{\int_{\tau_e^{-1}}^\infty \frac{T\rho(\omega)d\omega}{\omega}}{\int_{\tau_e^{-1}}^\infty \rho(\omega)d\omega} \approx \frac{T}{\omega_{\text{max}}} \ln(\omega_{\text{max}}\tau_e) \gg 1. \quad (6)$$

Remarkably, in higher orders with respect to $\rho(\varepsilon)$ the non-equilibrium heat flow $\dot{Q}$ differs from the equilibrium flow $\dot{Q}_0$ by the same factor (see supplementary material). This result holds even for a finite electric current flowing through the junction. However, in this case we need to replace the temperature $T$ by the effective temperature $T_{\text{eff}}$, see Eq. (2), of the tunneling electrons. Thus, the heat flow between the junction and the environment appears much larger than what the quasi-equilibrium estimates predict.

Ohmic approximation.— We now turn to the simplest case, an environment with a very high impedance
as compared to the quantum resistance, $R_Q$. In this limit tunneling electrons easily excite the environment modes. The spectral density $\rho(\omega)$ of these modes is sharply peaked at the zero frequency, $\omega = 0$. For the correlation function $J(t)$ in Eq. (3) the concentration of the environment modes at low frequencies implies that the expansion of $J(t)$ over $t$ up to the second order yields $J(t) \approx -iat - (b/2)t^2$, where the coefficients $a$ and $b$ are defined as $a = \int_{-\infty}^{\infty} (1 + N(\omega) - N(0))\rho(\omega)d\omega$ and $b = \int_{-\infty}^{\infty} \omega\rho(\omega)B_d d\omega$. Using this expansion for $J(t)$ we obtain the following result for the density function $P(\varepsilon)$

$$P(\varepsilon) = (1/\sqrt{2\pi b}) \exp\left[-(\varepsilon - a)^2/2b\right].$$

Here the expansion parameter $a$ can be estimated as follows $a = a_0 \left(1 + \frac{T_{\text{env}} - T_{\text{eff}}}{2} \frac{\text{Im}(\omega_{\text{max}} T_{\text{eff}})}{\text{Im}(\omega_{\text{max}} T_{\text{env}})}\right)$, where $a_0 = 2 \int \rho d\omega \approx 2\rho(0)\omega_{\text{max}} \approx 2E_c$ with $E_c$ being the charging energy of the tunnel junction, $T_e$ is the electron temperature in the junction, $T_{\text{env}}$ is the temperature of environment modes, $\omega_{\text{max}} \approx 1/(RT_F C)$. Similar for coefficient $b$ in Eq. (7) we obtain $b = b_0 (T_{\text{eff}} + T_{\text{env}})$

Substituting the density $P(\omega)$, Eq. (7), into the heat flux $\dot{Q}$, Eq. (1), we obtain our first main result for the typical heat exchange of the Ohmic environment with the tunnel junction between two normal leads. The full temperature and voltage dependence is shown in Fig. 3.

**Dynamic Coulomb interaction.** Next we discuss the more realistic situation where the tunneling junction is connected to two disordered conductors (leads). Following Ref. [8], one can find the spectral probability function $\rho(\omega)$ in Eq. (3) corresponding to the electron–environment interaction

$$\rho_{ij}(\omega) = \frac{\omega}{2\pi} \text{Im} \sum_q \frac{(\pi q)^2 (2\delta_{ij} - 1)\tilde{U}_{ij}(q, \omega)}{(q^2 - q + i\omega)(q^2 - q + i\omega)}.$$  

where $i, j = 1, 2$ are the lead indices, $D_{1,2}$ are diffusion coefficients within respective electrodes, and $\tilde{U}_{ij}(q, \omega)$ are the dynamically screened Coulomb interactions within (across) the electrodes. The form of spectral probability $\rho(\omega)$ $|\rho(\omega) - 2\rho_{12} + \rho_{11} + \rho_{22}|$ depends on the structure of the environmental excitations spectrum and, thus, on the external bias.

The system under consideration is shown in Fig. 4: two contacts are separated by distance $d$ and their thickness is $a$. The external bias is $V$ and the contacts are kept at temperature $T$ and the environment at temperature $T_{\text{env}}$. Two situations are possible: i) for zero bias, $V = 0$ we have $T_{\text{out}} = T_e = T_{\text{eff}}$ and $T_{\text{in}} = T_{\text{env}}$. ii) for $V \neq 0$ the effective temperature $T_{\text{eff}}$ depends on $V$ as shown in Eq. (2).

The screened Coulomb interaction in Eq. (3) in Fourier space has the form $\tilde{U}(q, \omega) = \{ U(0)(q, \omega) \}^{-1}$.
\begin{align*}
\mathcal{P}(\mathbf{q}, \omega)^{-1}, \text{ where } U^{(0)}(\mathbf{q}, \omega) = u(q) \mathcal{L} + v(q) \mathcal{S}, \text{ is the bare Coulomb interaction and } \mathcal{P}(\mathbf{q}, \omega) \text{ the polarization matrix respectively with } P_{ij} = \nu_i \mathcal{D}_i q^2 (\mathcal{D}_j q^2 - \omega)^{-1} \delta_{ij}, \nu_i \text{ is the electron density of states at the Fermi surface in lead } i.
\end{align*}

Below we concentrate on quasi 2D infinite leads. For this geometry with \( a \ll L \), where \( L \) is the characteristic lead size in the \( x \) and \( y \) directions, the bare Coulomb interaction has the form

\begin{align*}
U^{(0)}_{ij}(\mathbf{r}_i - \mathbf{r}_j) = e^2 \int dz_i dz_j \frac{\delta(z_i - z_j^{(0)}) \delta(z_j - z_j^{(0)})}{|\mathbf{r}_i - \mathbf{r}_j|},
\end{align*}

with \( z_j^{(0)} = (1/2 - \delta_{ij}) d \), leading to \( u(q) = 2\pi e^2/q \) and \( v(q) = 2\pi e^2 e^{-\nu} / q \).

In the following, we consider the case of identical leads with same diffusion coefficients \( D_1 = D_2 = D \) and densities of states, \( \nu_1 = \nu_2 = \nu \). The dimensionless matrix elements \( \tilde{U}_{ij} \) of the dynamically screened Coulomb interaction (in units of \( e^2 d \)) are then given by

\begin{align*}
\tilde{U}_{ii} &= 4\pi \frac{\chi(\tilde{q})}{\tilde{q}^2 (\tilde{q}) - \coth^{-2}(\tilde{q})}, \quad \tilde{U}_{ij \neq j} = \frac{\tilde{U}_{ii}}{\chi(\tilde{q}) \coth(\tilde{q})},
\end{align*}

where \( \tilde{q} = dq \) and \( \tilde{\omega} = \omega (d^2 / D) \) with the dimensionless function \( \chi(\tilde{q}) \equiv 1 + \coth(\tilde{q}) + \frac{4\pi^2 e^2}{\tilde{q}^2} \). Using these expressions, we can write Eq. (8) as

\begin{align*}
\rho(\omega) = \frac{2e^2 d}{D} \tilde{\omega} \text{Im} \int_0^\infty d\tilde{q} d\omega \tilde{U}_{11} \left[ 1 - (\chi(\tilde{q}) \coth(\tilde{q}))^{-1} \right] / (\tilde{q}^2 - \tilde{\omega}^2).
\end{align*}

Substituting Eq. (11) into Eqs. (3) we can calculate the heat flux \( \tilde{Q} \) in Eq. (1) between environment and nano-junction with dynamic Coulomb interaction. The typical energy scale is given by the Thouless energy for the junction of distance \( d \), \( E_{th} = D / d^2 \) which we use to rewrite all expressions in dimensionless units. For a typical temperature \( T_0 = 0.1E_{th} \approx 10K \), the temperature and voltage dependence is numerically calculated and shown in Fig. (3). Again, the non-equilibrium heat flow \( \tilde{Q} \) is up to an order of magnitude larger and the quasi-equilibrium approximation \( Q_0 \). We remark, that in this case the function \( \rho(\omega) \) introduces a natural cut-off for \( J(t) \), Eq. (3), which behaves as \( \sim - |t| \) for large \( t \).

**Discussion.** — Above we assumed that hot electrons interact with acoustic phonons (acoustic environment modes). This assumption holds if the environment temperature \( T_{env} \) is lower than the Debye temperature \( \Theta_D \), which is of the order of optical phonon energies. In this temperature range the electron interaction with the environment is quasi-elastic because the change of the electron energy, which is equal to the energy of the emitted or absorbed phonons is much smaller than the electron energy. Due to the small inelasticity of the acoustic phonon scattering, the deviation of the electron distribution function in the momentum space from the isotropic one is small even when the electrons become hot.

We also assume that the density of hot electrons is high enough so that the electron-electron scattering time \( \tau_{e-e} \) is smaller than the time of energy relaxation \( \tau_{env} \) (this time is large because of quasi-elastic nature of interaction between the electrons and environment). In this case the electron distribution function is close to an equilibrium one with an electron temperature \( T_e \), which is in high voltage limit is higher than the environment temperature \( T_{env} \). At very high applied voltages the electron energies become comparable with the energies of optical phonons (optical environmental modes) and the approximation of small inelastic scattering does not hold.

In summary, we discussed the influence of far from equilibrium heating effects on properties of nanojunctions. Based on a quantum-kinetic approach we calculated the non-linear heat flux between environment and junction. We showed that the resulting freezing or heating effect far from equilibrium are by orders of magnitude larger than estimates based on quasi-equilibrium environment theory. We obtained analytical results for the heat flow in an idealized high-impedance environment and demonstrated, numerically, that these results hold for the more general case of an environment with Coulomb interaction. We showed that the environment can be a very effective freezing agent if the effective temperature well exceeds the high frequency cut-off \( \hbar \omega_{max} \).

One can expect that our results, in particular the giant freezing effect, will be important for the electronic transport in junction arrays \([9]\), which will be subject of a forthcoming work.
