Abstract: A spectrum of massive graviton states is present in several recent theoretical models that include extra space dimensions. In some such models the graviton states are well separated in mass, and can be detected as resonances in collider experiments. The ability of the ATLAS detector at the Large Hadron Collider to identify such states and measure their properties is considered, in the case that the resonances are narrow compared to the experimental resolution. The discovery limits for the detection of the decay mode $G \rightarrow e^+e^-$ are derived. The angular distribution of the lepton pair is used to determine the spin of the intermediate state. In one specific model, the resonance can be detected up to a graviton resonance mass of 2080 GeV, while the angular distribution favours a spin-2 hypothesis over a spin-1 hypothesis at 90% confidence for resonance masses up to 1720 GeV.

Keywords: Hadronic Colliders, Beyond Standard Model, Extra Large Dimensions.
1. Introduction

The recently proposed localized gravity model of Randall and Sundrum [1] has aroused great theoretical interest, and many possible extensions and elaborations of this type of theory are being discussed in the literature [2]. The model was initially motivated because it solved the weak-Planck scale hierarchy via an exponentially suppressed warp factor in a non-factorisable geometry. Despite possible problems with negative tension branes and stability in some of the frameworks, these problems are solved in other models. For now, we ignore the details of particular models and concentrate on a measurement that should apply to a broad class of the models. Such scenarios are characterised by the existence of a series of graviton excitations, which may be detectable at present and future colliders. In some cases these excitations may be sufficiently well spaced to be detected as individual resonances.

This work will discuss the possibility of detecting such graviton resonances in as model independent a way as possible, using the scenario of [1] as a guide. However, the results derived do not depend on the validity of this particular scenario, but can be applied to any model giving rise to narrow graviton resonances.

In the scenario of [1] the massive graviton excitations couple with equal strength to the visible sector [3]. However, the higher modes being suppressed by the falling parton distribution functions, we consider only the lightest mode. This does not in any way affect the generality of our approach, as our analysis can be applied to any such resonances, including the higher modes, so long as the resonances are narrow and sufficiently separated from the other modes. This is in contrast to studies in which many excitations, each with small coupling, contribute to some scattering process [4].
An event generator capable of simulating the production and decay of spin-2 resonances has been developed. This generator is an extension of the HERWIG 6.1 [5] simulation package. The generated events are passed through the ATLAS fast simulation (ATLFAST [6]), in order to give a realistic description of detector resolution and efficiency. The decay channel $G \rightarrow e^+e^-$ is chosen for study, since the ATLAS detector has excellent energy and angular resolution for high energy electrons, and the Standard Model background comes dominantly from the well-understood Drell-Yan process. The observable cross section for this process is considered first, and limits on the discovery reach of ATLAS, based simply on the ability to detect the resonance above the Standard Model background, are derived. The angular distribution of the decay products is then considered, in order to study the ability of the detector to determine the spin of the resonance.

2. The event generator

In the model of [3], a 5-dimensional non-factorizable geometry is used, with two 3-branes of opposite tension. A graviton Kaluza-Klein spectrum is created, with a scale $\Lambda_\pi = \bar{M}_{Pl} e^{-kr_c\pi}$, where $\bar{M}_{Pl}$ is the reduced effective 4-D Planck scale, $r_c$ is the compactification radius of the extra dimension, and $k$ is a scale of the order of the Planck scale. The geometrical exponential factor (dubbed the ‘warp factor’) generates TeV scales from fundamental Planck scales and hence offers a solution to the hierarchy problem, if $kr_c \approx 12$. The masses of the graviton resonances are given by $m_n = k x_n e^{-kr_c\pi} = x_n (k/\bar{M}_{Pl})\Lambda_\pi$ where $x_n$ are the roots of the Bessel function of order 1. The couplings of the massive resonances are given by $1/\Lambda_\pi$. The properties of the model are determined by the ratio $k/\bar{M}_{Pl}$. We have chosen a value of 0.01 (at the bottom of the range suggested in [3]) for this ratio, which according to [4], is on the edge of 95% exclusion for a first graviton excitation mass of less than 2000 GeV. Thus, we assign a low coupling constant to the gravitons, and hence obtain a conservative estimate of the production cross section. This choice leads naturally to narrow resonances. This test scenario is used to illustrate the potential physics reach.

The implementation of the resonance is largely model independent, depending only on a universal coupling to the Standard Model fields. This is generally the case for models deriving from extra dimensions, and the effective Lagrangian is given at first non-trivial order in $1/\Lambda_\pi$ as:

$$\mathcal{L}_I = -\frac{1}{\Lambda_\pi} h^{\mu\nu} T_{\mu\nu}, \quad (2.1)$$

where $h^{\mu\nu}$ is the spin-2 field and $T_{\mu\nu}$ is the energy-momentum tensor of the Standard Model fields. Here, we consider only the production and measurement of the lightest massive graviton excitation. We note however [3], that other heavier resonances are
expected. In the case we consider here, they are well split in mass and hence the
lightest resonance will be produced dominantly.

The decay $G \rightarrow e^+e^-$ is treated in the HERWIG implementation as a $2 \rightarrow 2$
process, consisting of the two hard production subprocesses $q\bar{q} \rightarrow e^+e^-$ and $gg \rightarrow e^+e^-$. For the $q\bar{q} \rightarrow e^+e^-$ channel we do not consider interference with the Standard
Model Drell-Yan subprocesses as the interference is negligible for our purposes. The
code is available from the authors on request.

For calculating the matrix elements and the total decay width of the graviton
resonance, we made use of the results in \cite{8, 9, 10}. We carried out our calculations
both by hand and by using HELAS \cite{11} incorporating subprograms with spin-2 par-
ticles \cite{12}. Our implementation of the decay widths corrects a typogra phical error
in \cite{8} for the decay into heavy vector bosons but this has only a small effect on the
total decay width.

$$\Gamma(G \rightarrow VV) = \frac{\delta m_G^3}{40\pi \Lambda^2} \left(1 - 4r_V\right)^{1/2} \left(\frac{13}{12} + \frac{14}{3}r_V + 4r_V^2\right), \quad (2.2)$$

where, as in \cite{6}, $\delta = 1/2$ for identical particles and $r_V = m_V^2/m_G^2$.

The angular distributions of the possible subprocesses, in the centre-of-mass
frame of the resonance, are shown in Table 1. Here $\theta^*$ is the angle between the decay
electron and the beam direction in the dilepton centre-of-mass frame. The spin-2
distributions contrast strongly with the angular distributions resulting from spin-1
or scalar resonances. These distributions are shown in Figure 1.

| Process | Distribution |
|---------|--------------|
| $gg \rightarrow G \rightarrow e^+e^-$ | $1 - \cos^4 \theta^*$ |
| $q\bar{q} \rightarrow G \rightarrow e^+e^-$ | $1 - 3 \cos^2 \theta^* + 4 \cos^4 \theta^*$ |
| $q\bar{q}, gg \rightarrow V \rightarrow e^+e^-$ | $1 + \alpha \cos^2 \theta^*$ |
| $q\bar{q}, gg \rightarrow S \rightarrow e^+e^-$ | $1$ |

Table 1: Angular distributions in graviton ($G$), vector ($V$) and scalar ($S$) boson production
and decay. $\alpha = 1$ in Standard Model processes.

3. Detection of the graviton resonance

The process $pp \rightarrow G \rightarrow e^+e^-$ must be detected above the background from the
Standard Model processes $pp \rightarrow Z/\gamma^* \rightarrow e^+e^-$. Samples of events were generated for
a single graviton excitation with a mass ranging from 500 GeV to 2.2 TeV. The masses
and widths of the graviton resonances are given in Table 2, as they are computed
with the model parameters given above. The table also shows the cross-section times
branching ratio $\sigma \cdot B$ in the test model and the width of the resonance reconstructed
after the ATLAS detector simulation. In all the cases studied, the true width of the
resonance is much smaller than the Gaussian experimental resolution $\Gamma_m$ and can be neglected. Hence the results are valid for any model in which this condition is met. In our test model, this is the case for $k/\bar{M}_{Pl} < 0.06$, at which point the width is approximately equal to the experimental resolution, and the cross section is 36 times larger than we have assumed. For larger values of $k/\bar{M}_{Pl}$, the very high signal cross sections would overwhelm the Standard Model background, making the resonance very easy to detect, and the spin simple to determine, even with a large width.

For each mass point, having determined the observed resonance width $\Gamma_m$, a mass window is defined as $\pm 3\Gamma_m$ around the graviton mass. The Drell-Yan cross-section inside this mass window is then calculated using the HERWIG 6.1 event generator [5]. The number of background events expected in the mass window is then computed, for an integrated luminosity of 100 fb$^{-1}$, corresponding to one year of LHC running at design luminosity. The ATLFAST simulation of the ATLAS detector is used to compute the acceptance for the process, which is dominated by the pseudorapidity ($\eta$) coverage of the tracker, $|\eta| < 2.5$. Cuts are also made on the isolation of the electrons to account for the effect of nearby hadrons on the detection efficiency. In addition to the cuts imposed by ATLFAST, a tracking efficiency of 90% was applied to each electron, to allow for track reconstruction losses which are not included in ATLFAST. These losses are estimated in [13] to be approximately
Table 2: Masses $m_G$ and widths $\Gamma_G$ of the simulated graviton resonances, and the Gaussian width of the observed resonance $\Gamma_m$ after detector effects. $\sigma \cdot B$ is the cross-section times branching ratio in the test model.

5% at high transverse momentum if the tracks are well isolated. Our efficiency value is therefore conservative. The number of Drell-Yan background events ($N_B$) inside each mass window after these cuts is given in Table 3.

Table 3: The number of signal events in the test model, $N_S$, expected inside each graviton mass window in a run of 100 $fb^{-1}$, after detector effects; the number of Standard Model background events, $N_B$; the minimum number of signal events required to detect the resonance, $N_S^{\text{min}}$; and the minimum production cross-section times branching ratio $(\sigma \cdot B)^{\text{min}}$ required to detect the resonance via $e^+e^-$ production.

The expected signal in the test model for $m_G = 1.5$ TeV can be seen in Figure 2, showing the data expected for 100 $fb^{-1}$ of integrated luminosity. The signal is prominent above the small Standard Model background.
Figure 2: The number of events per 4 GeV mass bin from a graviton resonance, with $m_G = 1.5$ TeV (signal), superimposed on the expected Standard Model background (SM), for 100 fb$^{-1}$ of integrated luminosity. The mass window used to select the signal is indicated by arrows.

We now consider the model-independent detection limit for such a resonance. The minimum number of signal events, $N^\text{min}_S$, needed to detect the resonance above the background is taken to be $5\sqrt{N_B}$ or 10 events, whichever is greater, in order to ensure that the signal is statistically significant. The minimum cross-section times branching ratio required to produce this number of events is also given in Table 3, after correcting for the detector acceptance and efficiency, and assuming an integrated luminosity of 100 fb$^{-1}$.

It can be seen from these results that the background becomes negligible for graviton masses above 1800 GeV. It should be emphasised that these results are independent of the test model, and rely only on the assumption that the width of the resonance to be detected is negligible compared to the detector mass resolution. However, as an example, we can compare this cross-section limit with the values predicted by our test model, in order to determine the physics reach for ATLAS for this specific case. This is done in Figure 3, which displays $\sigma \cdot B$ for the test model and $(\sigma \cdot B)^\text{min}$. The test model could be detected for graviton masses up to 2080 GeV. Using Figure 3, similar estimates of the ATLAS search reach for other models can be determined without repeating the detector simulation or background analysis.
The search reach for other collider experiments, such as CMS, would require a new simulation with the appropriate mass resolution.

Our results differ from those in [13] for the case of a $Z'$ with Standard Model couplings, both because of the acceptance difference arising from the spin of the resonance, and the $Z'$ width, which exceeds 50 GeV for a $Z'$ mass of 2 TeV.

![Graph](image)

**Figure 3:** The cross-section times branching ratio, $\sigma \cdot B$, for $G \rightarrow e^+e^-$ in the test model and the smallest detectable cross-section times branching ratio, $(\sigma \cdot B)^{min}$

4. Angular distributions

In order to demonstrate that the observed resonance is a graviton and not due to a spin-1 $Z'$, or similar exotic object, it is necessary to show that it is produced by a spin-2 intermediate state. The strong differences between the angular distributions shown in Figure [4] would allow the spin of the resonance to be determined given sufficient statistics. Information can also be gained on the relative production rate from the $gg$ and $q\bar{q}$ processes.

Figure [4] shows the angular distribution expected in the test model for a graviton resonance mass of 1.5 TeV, after passing the events through the detector simulation and analysis cuts, using the statistics for 100 fb$^{-1}$ of data. The contributions from Standard Model Background, $gg$ production and $q\bar{q}$ production of the graviton resonance are shown. In this case, 83% of the graviton production is from the $gg$ process.
The distribution expected from a spin-1 resonance is also shown. The cutoff in the detector acceptance at $|\eta| = 2.5$ removes events at large $|\cos \theta^*|$. For heavy gravitons, which are produced with little longitudinal momentum, the effect is relatively sharp in $\cos \theta^*$, while for lighter gravitons and Drell-Yan processes, the acceptance loss reaches to lower $|\cos \theta^*|$ values.

![Figure 4:](image)

**Figure 4:** The angular distribution of data (points with errors) in the test model for $m_G = 1.5$ TeV and 100 fb$^{-1}$ of integrated luminosity. The stacked histograms show the contributions from the Standard Model (SM), $gg$ production ($gg$) and $q\bar{q}$ production ($q\bar{q}$). The curve shows the distribution expected from a spin-1 resonance.

A likelihood function was constructed to quantify the information in the angular distributions, defined as

$$L = x_q \cdot f_q(\theta^*) \cdot A_q(M, \theta^*)/I_q(M) + x_g \cdot f_g(\theta^*) \cdot A_g(M, \theta^*)/I_g(M)$$

$$+ x_{DY} \cdot f_{DY}(\theta^*) \cdot A_{DY}(M, \theta^*)/I_{DY}(M)$$

(4.1)

where $x_i$ is the fraction of the events from each contributing process, $f_i(\theta^*)$ is the angular distribution of the process, $A_i(M, \theta^*)$ is the acceptance of the detector as a function of the mass of the electron pair and $\theta^*$, and

$$I_i(M) = \int_{-1}^{1} f_i(\theta^*) \cdot A_i(M, \theta^*) \, d\cos \theta^*$$

(4.2)

$i = q, g, DY$ for the processes $q\bar{q} \rightarrow G$, $gg \rightarrow G$, and $q\bar{q} \rightarrow Z/\gamma^*$ respectively. Only the shape of the distribution is used in the statistical tests, and the coefficients $x$ are
constrained such that

\[ x_q + x_g + x_{DY} = 1 \]  \quad (4.3)

In order to evaluate the discovery reach of the experiment, in terms of its ability to reveal the spin-2 nature of the resonance, the following procedure was followed, intended to mimic an ensemble of possible experimental runs:

1. N events were generated, containing the expected number \( N_{DY} \) background events, with a Poisson distribution, and the remainder being graviton resonance decays with the \( q\bar{q} \) and \( gg \) mixture of the test model at that mass point.

2. \( -\log L \) was evaluated for two hypotheses:
   
   (a) \( x_q = x_g = 0, x_{DY} = 1 \), corresponding to a spin-1 resonance, such as a \( Z' \)
   
   (b) all the coefficients set to the values in the test model with the expected Standard Model background fraction.

3. \( N \) was increased by adding graviton resonance events, until the difference in \( -\log L \) between the two hypotheses reached 1.34, then 1.92 and finally 3.32. At these points the spin-1 hypothesis can be eliminated with 90, 95 and 99% confidence respectively.

4. This procedure was repeated for many sets of events, and the average value of \( N \) needed for discrimination was found for each confidence level.

This value of \( N \) provides a measure of the statistics needed in a typical experiment in order to determine the spin-2 nature of the resonance. \( N_S^{\text{min}} = N - N_{DY} \) is the number of signal events in the sample at the confidence limit. Table 4 shows results of this procedure.

The 90% confidence limit for \( m_G = 500 \text{ GeV} \) is raised by the requirement that the sample contains at least \( 5\sqrt{N_{DY}} \) signal events. In this case, less events would be sufficient to establish the spin of the resonance, but would not meet our criterion for a discovery. At very high \( m_G \), the discrimination becomes more difficult because of the increased fraction of the resonance production coming from the \( q\bar{q} \) initial state.

Figure 5 shows the confidence limit curves and the corresponding cross-section times branching ratio in our test model. Smooth curves have been drawn through the points since some statistical fluctuations remain at high mass. These results are model independent, as long as the assumption that the coupling of the graviton resonance is universal holds true. This assumption affects the fraction of graviton resonance production from \( gg \) and \( q\bar{q} \) initial states, and hence the shape of the angular distribution. The cross-section times branching ratio of the test model is shown for comparison. In this model, the spin of the resonance could be determined with 90% confidence for graviton resonance masses as high as 1720 GeV.
### Table 4: The minimum numbers of signal events, $N^\text{min}_S$, needed to distinguish the spin-2 and spin-1 hypotheses at 90, 95 and 99% confidence, and the corresponding cross-section times branching ratio, for a run of 100 fb$^{-1}$.

| $m_G$ (GeV) | $N^\text{min}_S$ | $\sigma \cdot B$ (fb) |
|------------|-----------------|----------------------|
|            | 90% CL | 95% CL | 99% CL | 90% CL | 95% CL | 99% CL |
| 500        | 140     | 141    | 226    | 1.90   | 1.92   | 3.07   |
| 1000       | 59      | 70     | 99     | 0.80   | 0.94   | 1.33   |
| 1500       | 43      | 48     | 70     | 0.61   | 0.68   | 1.00   |
| 1700       | 41      | 48     | 65     | 0.61   | 0.71   | 0.96   |
| 1800       | 29      | 33     | 58     | 0.43   | 0.49   | 0.87   |
| 1900       | 32      | 40     | 64     | 0.49   | 0.61   | 0.98   |
| 2000       | 36      | 41     | 69     | 0.56   | 0.64   | 1.08   |
| 2100       | 31      | 45     | 59     | 0.49   | 0.71   | 0.93   |
| 2200       | 29      | 33     | 55     | 0.45   | 0.52   | 0.86   |

### Figure 5: The smallest cross-section times branching ratio for which the spin-2 hypothesis is favoured over the spin-1 hypothesis at 90, 95 and 99% confidence. The cross-section times branching ratio of the test model is also shown.

5. Conclusions

The discovery limits for the detection of the decay mode $G \rightarrow e^+e^-$, derived above,
show that the resonance can be detected up to a graviton resonance mass of 2080 GeV in our test model. The limits are model independent as long as the graviton couplings are universal and give rise to narrow resonances, with widths less than the experimental resolution. The angular distribution of the lepton pair can be used to determine the spin of the state. In our test model, the angular distribution favours a spin-2 hypothesis over a spin-1 hypothesis at 90% confidence for graviton masses up to 1720 GeV. Once the spin of the resonance has been determined, it will be useful to check the universality of its couplings \cite{14}. Muon and jet production cross-sections in the resonance region as well as decays into photons, massive vector bosons, higgs bosons and top quarks could be used to check this universality. The bosonic final states would provide a further test of the spin, since their angular distributions will be different from that of the electrons considered above. They would also serve to rule out other models of high mass resonances. For example, the $Z'$ will not couple to a two photon final state.

Acknowledgments

We would like to thank J. March-Russell for an interesting discussion and I. Vernon for helpful discussions on different scenarios. MAP would like to thank C.G. Lester for his technical help. This work was funded by the U.K. Particle Physics and Astronomy Research Council.
