Abstract

Various anesthetic options are known in the field of dentistry. The most frequently used techniques are the infiltration anesthesia (IA) and the inferior alveolar nerve block (IANB). However, both methods are characterized by a long-lasting action, mostly longer than needed, and possible significant complications like nerve injuries. Moreover, as patients are getting older, cardiovascular and medicinal issues have to be taken into account when dental anesthesia is performed. A less known and used technique is represented by the intraligamentary anesthesia, which has unique characteristics and advantages. This special technique, its effect on the periodontal tissues, advantages and disadvantages including contraindications are discussed in the present paper.

Introduction

A successful pain management through efficient local anesthesia is the basis for every dental therapy. On the one hand, patients expect a painless and comfortable dental treatment, which becomes crucial especially in subjects suffering from dental phobia [1]. On the other hand, the skill of a dentist or oral surgeon himself is often measured by the ability of achieving profound and successful local anesthesia and pain relief. There are different, more or less known options of local anesthesia in the dental area, first of all infiltration anesthesia (IA) as well as the inferior alveolar nerve block (IAN). While IA interrupts the pain perception in the area of injection, the second mentioned technique is related to the innervation area of the mandibular nerve. Indeed, beside the interruption of pain perception, both local anesthetic methods block also the function of sensitive and motor nerves [2]. As a consequence patients experience loss of sensitivity as well as total or partial loss of function of facial muscles and/or the tongue for the duration of the anesthesia [5]. The result is a temporary restriction of patients’ daily life with reduced ability in speaking and eating, but also the risk of bite and burn injuries. Moreover, it is well known, that a rare but major complication of IANB is represented by the lesion of the surrounding tissues [5]. In 1920 Chompret published his experiences entitled his work “Anesthésie par injections intraligamentueuses” [6]. During the following decades the described technique of intraligamentary anesthesia (ILA) was refined simultaneously to the development of new anesthetical devices. These instruments enabled the injection of the anesthetic solution in the periodontal ligament against the high periodontal tissue resistance (back-pressure) with only little effort by the dentist himself. Meanwhile various injection devices are available, both as manual instrument (as pistol-type, penholder grip syringe or dosing wheel syringe) as well as computer-controlled systems (CCCLADS: computer controlled local anesthetic delivery system) [7]. Figure 1 shows an example of a penholder grip syringe armamentarium.

ILA-technique

All of the mentioned devices are characterized by the same working principle [5]. The ILA starts with needle (27-30G, 0.3-0.4mm in diameter) insertion in the periodontal ligament space between the root of the tooth and the alveolar bone. The needle is inserted at an angle of 30-40 degrees in respect to the long axis of the tooth and should reach a subgingival depth of about 2 to 3 mm in periodontal healthy individuals (Figure 2). At least 0.2ml anesthetic solution should be applied for each injection site, whereby single rooted teeth should be anesthetized with two injections, multi-rooted teeth with one injection per root. The injection time for the first application should reach at least 20 seconds, whereas every following injection for the same tooth should last few seconds longer. Histologic studies have shown that the anesthetic solution diffuses into the alveolar bone after application, a process that needs time in order to overcome tissue resistance and avoid an overpressure in the periodontal complex. In case of any overhasty injection, extrusion of the respective tooth with a premature contact due to hydraulic forces may be the consequence.

Anesthesia is achieved to the tooth itself but also to the directly surrounding tissues, fundamental especially in case of extractions [8,9]. The onset of a successful in anesthesia may be expected after about 40 seconds, the average duration is of about 30 minutes, sufficient for most dental treatments, regardless of conservative, prosthetic or endodontic procedures or extractions. If a longer duration is necessary, re-injection
is possible, although paying attention regarding the injection time (>20 seconds).

Periodontal effects of ILA

There is still skepticism regarding the possible negative consequences of ILA on the periodontium. In the last decades several authors conducted animal studies in order to investigate the short- and long-term effect of ILA on the periodontal ligament histologically. Every study described a temporary inflammatory response in the first 24 hours after ILA. However, none of the authors could find a permanent damage of the periodontium after this initial reaction, neither with respect respect to soft tissue (periodontal fibers, gingiva) yet on hard tissue (alveolar bone) [10-13].

Similarly, the possible association between ILA and the occurrence of a dry socket after extraction has been widely studied. No investigation could detect a significant relation between the anesthetic methods and wound healing disorders in terms of dolor post extractionem [14,15].

Undesirable side effects

Among the described temporary undesirable side effects after intraligamentary injection, postoperative pain due to high pressure during injection as well as tooth extrusion with premature contact are most frequent. Both complications are a consequence of a too fast and too forceful injection. As a result, the anesthetic solution cannot diffuse in the periodontial tissue and the alveolar bone, as described above. As liquids are not compressible, the tooth is pressed out of the alveolar compartment and extruded towards the oral cavity by a “hydraulic leverage” [16]. Occlusal precontacts may be the final result. In summary, these complications are not technique-dependent but operator-dependent, as they can be avoided with accurate consideration of the injection features, especially the injection time.

Advantages of ILA

Due to the limited anatomical range and the limited duration of action of 30 minutes, the ILA offers the user some advantages both to the patient and the dentist. Postoperative restrictions (speaking, eating, drinking) are missing, patients following a dental treatment under ILA are not restricted regarding their daily life activities or their occupational obligations. Simultaneously, ILA prevents postoperative bite or burn injuries, which can be the consequence of prolonged loss of sensitivity for example after IANB. In addition, the localized anesthetic effect of ILA allows for treatments in different regions (e. g. left and right mandibular molars) in the same session. Since the onset of the anesthetic effect is reached almost immediately after injection, there is no latency between anesthesia and treatment, like it has to be taken into account for IA and IANB. Moreover and in contrast to IANB, there is no risk for nerve injuries by intraligamental injections [17].

Finally, ILA allows for a significant reduction of the total amount of both anesthetic solution and vasoconstrictor supplement compared to other anesthetic methods. Simultaneously, accidental intravascular application is avoided. Due to these characteristics, intraligamental anesthesia is advantageous especially in the treatment of multimorbid “high-risk patients” (e. g. patients with cardiovascular disease or anticoagulation) [8].

Contraindications

Given the fact, that according to the present literature negative long term effects of ILA may be excluded, there are still some contraindications that must be taken into account. In the late 80s Rahn et al. found a potentially high rate of bacteremia of 61% in patients treated with ILA [18,19]. They could decrease significantly this rate by a preoperative mouthwash with chlorhexidine for 30 seconds. However, ILA represents still a hazardous method for patients with the risk of Endocarditis or immunosuppressed patients. Moreover, in case of a profound marginal periodontitis or in teeth with a sclerotic periodontal gap, the usefulness of ILA is reduced and alternative anesthetic techniques (IANB, IA) are recommended.

Conclusion

In summary, intraligamental anesthesia can rated as efficient as infiltration anesthesia or inferior alveolar nerve block. Numerous investigations have demonstrated the feasibility of ILA for most dental routine treatments, whereas the patients additionally benefit from the mentioned advantages of this technique. Accordingly, as minimally invasive method of dental anesthesia represents a clear benefit for both practitioners and patients.
