(Received: March 11, 2019; revised manuscript received: May 6, 2019; accepted: July 28, 2019)

Purpose: The aim of this study was to determine the effect of training intensive care unit (ICU) nurses in reducing ventilator-associated pneumonia (VAP). Materials and methods: A quasi-experimental (single group, pre-test–post-test) model was used. The study was conducted in 2015, in nine adult ICUs in Istanbul, where we observed the VAP rate and trained study group nurses. Sixty nurses were given two VAP training sessions (averaging 45 min each) at intervals of 6 months. Forty-nine nurses were in the control group. Data were collected with an Introductory Information Form, a VAP Information Test, and an Application Status of VAP Preventive/Reducing Initiatives Form. The incidences of VAP in 2014 and 2015 were also compared. Frequencies, percentages, means, standard deviations, t-tests, Wilcoxon tests, and χ² tests were used to evaluate the data. The values of p less than .05 were considered significant. Results: The mean-total-knowledge score increased significantly in the study group. The application of preventive/reducing initiatives also increased significantly in the study group, but in the last measurement, the difference between the groups was not statistically significant. The incidences of VAP decreased significantly in the study group. Conclusion: This study showed that the VAP training given to intensive care nurses increased their knowledge level and decreased the incidence of VAP in their ICUs.

Keywords: education, infection control, nursing, ventilator-associated pneumonia, intensive care

INTRODUCTION

Ventilator-associated pneumonia (VAP) is pneumonia that occurs within 48 hr after the intubation of intensive care patients [1–4]. Because the VAP rate depends on a number of factors, such as age, days of mechanical ventilation, and chronic diseases, the real incidence of VAP is difficult to determine [1], but in the literature [1, 3–5], it is considered to be high. In studies conducted in Egypt, Iran, China, the United States of America, and Turkey, the VAP rate per 1,000 mechanical ventilator days was found to be 70.3, 21.08, 29.5 (13.4 medical/surgical ICU and 23.7 medical ICU), and 31.2, respectively [6–8]. The rate of mortality related to VAP is also high. For example, the mortality rate is 35.3% in Finland, 53% in Jordan, and 24.5% in Turkey [5, 9, 10].

Although VAP has high morbidity and mortality rates, it is reported that these rates can be reduced by 20% with appropriate initiatives. These include the training of health workers, hand hygiene, semi-recumbent positioning (30°–45°), use of chlorhexidine gluconate in oral care, aspiration of subglottic secretions, use of a closed aspiration system, monitoring of gastric residual volume, control of the endotracheal tube cuff pressure, and suitable replacement of ventilator circuits [8, 11, 12]. It is understood that most of the interventions to prevent VAP are closely related to nursing interventions. For this reason, it is emphasized that training health workers, especially nurses, in VAP interventions, and increasing their level of knowledge on this subject, play very important roles [13–15]. It is reported, however, that intensive care nurses have low-level or moderate awareness, knowledge, attitude, and harmony about evidence-based practices to prevent VAP [12, 16–20].

It is therefore important to train nurses on this subject and to repeat this training at certain intervals to reduce the VAP rate [16, 17, 21]. It has been shown that training given to intensive care nurses in VAP increased the level of knowledge and harmony in nurses, and thus reduced the VAP rate. Moreover, it has been reported that there is a great need for multicentered studies on this subject, and that an increase in the number of studies strengthens the effect of the care in reducing the VAP rate [8, 17, 18, 22, 23].

In light of this information, when it was also considered that nurses in Turkey have different educational levels, and that there are many difficulties in the delivery of qualified care in Turkey, this study was conducted to determine the effect of the training given to nurses in reducing the VAP rate in adult ICU patients.

RESEARCH HYPOTHESES

H1: The knowledge level of VAP in nurses with training will be higher than those without training.

H2: The application of preventive/reducing nursing initiatives for VAP in nurses with training will be higher than those without training.

H3: After VAP training is given to intensive care nurses, the rate of VAP in their ICUs will be lower than in ICUs with untrained nurses.

MATERIALS AND METHODS

Design

A quasi-experimental model (pre-test/post-test control-group design with non-randomized groups) was used in this study.

Sample and settings

The study was conducted in nine adult ICUs in five tertiary-care hospitals in Istanbul between January 1, 2015 and January 30, 2016. We aimed for at least 50 nurses in the study group and 50 nurses in the control group. The third-level ICUs where the VAP rate was observed, permitting the conduct of the study, were included in the study. First and second level, paediatric and neonatal ICUs, and ICUs that do not allow the study are excluded. The ICUs were selected using a purposeful sampling method, considering the number of working nurses. We aimed to reach all the nurses in these ICUs, as it was thought the number of nurses might decrease. To reach the number of samples, more intensive care units (ICUs) were included in the study. Therefore, six ICUs were used for the study group and three for the control group. A total of 220 nurses were reached, but due to reasons such as maternity leave, military service, and leave, it was not possible to reach the ICU nurses in more than one ICU (approximately 1.5 months later), they were trained immediately before the start of the training. The training (averaging 45 min per session) was presented in the form of a Power-Point Presentation, given by the researcher in an interactive manner. After the training was completed, the nurses were asked to retake the VAP Information Test.

The first training. The nurses filled out all the forms immediately before the start of the training. The training (averaging 45 min per session) was presented in the form of a Power-Point Presentation, given by the researcher in an interactive manner. After the training was completed, the nurses were asked to retake the VAP Information Test.

The second training. It was carried out 6 months after the first. The stages of the first training were repeated. Since it was possible to reach the ICU nurses in more than one training program, the information booklet was distributed after all the nurses were trained, and the informational posters were hung in working areas where the nurses could always see them. After the clinical orientation program was conducted for the nurses who had just begun to work in the ICU (approximately 1–1.5 months later), they were trained in the same way.

The last measurement. The nurses were asked to refill the questionnaires 6 months after the second training. Two hundred and twenty nurses were trained over the year, but only data on those who participated in all phases of the study (60 nurses) were used. No training was given to the control group, but the nurses filled out all the forms in January and December of 2015. Only data from those in the control group who completed the questionnaires twice were used.
Since the Infection Control Committees of the Hospitals reported that they could give the annual incidence of VAP in the ICUs, data for the VAP rates in 2014 and 2015 were compared. However, since the diagnostic criteria for VAP changed in 2015 in one of the ICUs in the control group, the data for that VAP rate could not be used.

Data analyses

All analyses were performed using Statistical Package for the Social Sciences (SPSS, IBM Corp., IBM SPSS Statistics for Windows, Armonk, NY, USA), software package version 22.0. Frequencies, percentages, means, standard deviations, t-tests, Wilcoxon tests, and $\chi^2$ tests were used to evaluate the data. It was considered statistically significant when the two-sided $p$ value was lower than .05. The presence of a statistically significant difference between the groups in terms of continuous variables was examined with the Student’s t-test for parametric variables. The analysis of non-normally distributed variables was performed using non-parametric methods. The Wilcoxon test was used to compare intergroup non-parametric ordinal variables. The $\chi^2$ test was used to assess whether there was a difference between the two groups.

RESULTS

Demographics

There was no statistically significant difference between the groups in terms of their features (age, gender, etc.), other than marital status ($p > .05$). It was determined that the groups showed an equal distribution in terms of identifying characteristics (Table 1).

Knowledge level

Initially, the mean scores of the knowledge level were low in both groups (14.050 ± 2.295 in the study group; 15.080 ± 2.691 in the control group). The mean scores at the last measurement in both groups were higher at a statistically significant level than the mean scores at the first measurement in both groups ($p < .05$; Table 2), but the mean score at the last measurement in the study group was higher at a statistically significant level than the mean score at the last measurement in the control group ($p < .05$; Table 2).

The first and second post-training mean scores were higher at a statistically significant level than the first and second pre-training mean scores in the study group. Moreover, the last measurement mean score was lower at a statistically significant level than the second post-training mean score ($p < .05$; Table 3). It was therefore determined that the level of knowledge increased significantly after each training session, and the level of knowledge decreased significantly in 6 months after each training session ($p < .05$; Table 3).

Preventive/reducing initiatives

Initially, the total mean scores for all the initiatives were low in both groups (40.133 ± 5.147 in the study group; 41.551 ± 5.937 in the control group). At the first measurement, it was notably found that use of the closed aspiration system, aspiration of subglottic secretions, and use of mechanical ventilation (MV) weaning protocol initiatives were frequently applied by both groups (Table 4).

At the last measurement, the mean scores for these three initiatives were statistically significantly higher than the initial scores in the study group; the mean score for the MV weaning initiative was also significantly higher in the control group ($p < .05$). The total mean scores for all the initiatives at the last measurement in both groups were significantly higher than at the first measurement; however, there was no significant difference between the study and control groups ($p > .05$; Table 4).

For the study group, the mean scores of nine initiatives at the last measurement were significantly higher than before the first training ($p < .05$). The mean total scores at the last measurement were higher at a statistically significant level than the mean total scores before the first training ($p < .05$). Moreover, it was seen that semi-recumbent positioning, oral care, the administration of normal saline during aspiration, and confirming feeding tube placement were at the desired level (Table 5).

VAP incidence

In both the study and control group ICUs, the mean VAP rate in 2014 was higher than it was in 2015 ($p < .05$). Although the VAP rate was lower in the control group ICUs in 2014, it was lower in the study group ICUs in 2015 (Table 6).

DISCUSSION

This study was conducted to determine the effect of training given to nurses to reduce the VAP rate in adult ICUs. There was no statistically significant difference in descriptive characteristics between the study and control groups except for marital status. The number of married nurses was significantly higher in the study group, and the number of single nurses was significantly higher in the control group. However, the marital status of the nurses was not seen as a feature that could influence our research hypotheses positively or negatively.

Increasing ICU nurses’ knowledge of VAP and implementation of evidence-based applications in the care environment are the effective way to prevent VAP [30]. In the literature, in studies where ICU nurses’ knowledge of VAP prevention was evaluated, nurses’ knowledge of VAP was reported to be inadequate [17, 22, 31, 32]. In this study, the mean scores before the first training in the study group and the mean scores at the first measurement in the control group were found to be low on the VAP Information Test. This finding supports the findings of other studies. It can be concluded that ICU nurses are not aware of VAP prevention/reducing initiatives and that the lack of knowledge in this field should be eliminated.

It is clear that the knowledge and application levels of VAP initiatives by nurses can be increased with training [17, 19, 33–35]. In studies where training initiatives for preventing VAP were studied, the level of nurses’ knowledge and awareness of VAP, and their compliance levels for
the care bundle were increased, and the incidence of VAP was decreased [3, 16, 18, 26]. It was determined in this study that the mean scores at the last measurement in the study and control groups were higher at a statistically significant level. Moreover, the post-training mean scores were higher than the pre-training mean scores on the VAP Information Test in the study group. It was found that there was a statistically significant decrease in the knowledge level of the nurses during 6 months between trainings (Table 2). There was a significant difference in favour of the study group in terms of the distributions of the nurses in the study and control groups according to their descriptive characteristics.

Table 1. The distributions of the nurses in the study and control groups according to their descriptive characteristics

| Features                              | Groups                                  | Study group (n = 60) | Control group (n = 49) | χ²   | p    |

Note. Bold values represent statistically significant. χ²: chi-square test; ICU: intensive care unit; VAP: ventilator-associated pneumonia.
of the effectiveness of the training given for preventing VAP. This supports the results of previous studies reporting that training was important and effective in increasing the knowledge levels of nurses on VAP and also it confirms our H1 hypothesis. However, the findings that show a decrease in the knowledge level of the nurses on the VAP Information Test during 6 months between trainings can be interpreted as that the training given to nurses for VAP should be repeated at least every 6 months. The increase in the mean scores of the control group gives the impression that the applied information test creates awareness and therefore nurses try to learn by themselves.

It has been reported that VAP incidence can be reduced by 20% with basic and appropriate infection control measures [14, 24, 27, 36]. However, it was found in the study conducted on nurses by Bagheri-Nesami et al. [33] that the implementation of all preventive/reducing initiatives was rather low. In studies where the effect of the training given to nurses on the implementation levels of VAP preventive initiatives was examined, it was shown that the implementation levels of these initiatives were increased at a statistically significant level in nurses [21, 37, 38]. In this study, of nurses in the study group, the mean scores of the implementation of three initiatives were increased at the last measurement. In this study, the obtained data on the increase in the implementation levels of VAP preventive/reducing nursing initiatives in both groups (especially in the study group) support literature data. However, the difference between the groups was not statistically significant and the H2 hypothesis was rejected.

It is reported that the use of the closed aspiration method is important in preventing/reducing VAP. However, the vast majority of the nurses used an open aspiration system at the beginning of our study. As Ozden [39] has stated, this result can be caused by the difficulty in manipulating the catheter of a closed system. With an open system, however, the secretions cannot be aspirated enough. Moreover, it is emphasized that a closed system is less risky than an open aspiration system in terms of preservation of the hemodynamic balance of the patient, cost reduction, and VAP development. It can be said that informing nurses about the benefits of the closed aspiration method and encouraging them to use it are necessary and important.

We saw an increase in the implementation levels of VAP preventive/reducing initiatives in the control group. It is believed that this was caused by the increased awareness level on the subject because they knew that the tests applied in the study would be reapplied later, and they directed themselves to read and do research to get a higher score on the next test. The trained nurses in the ICUs also may have behaved more carefully and directed other nurses.
Table 4. The distribution of the mean scores at the first and second measurements for the nurses in the study and control groups in terms of the application status of VAP preventive/reducing initiatives

| Initiatives                                | Study group (before first training; n = 60) | Control group (first measurement; n = 49) | Study group (Last measurement; n = 60) | Control group (last measurement; n = 49) |
|--------------------------------------------|--------------------------------------------|------------------------------------------|---------------------------------------|------------------------------------------|

Training for reducing ventilator-associated pneumonia

Table 6. The mean VAP rate for 2014 and 2015 in the ICUs in the study and control groups

| Groups        | N  | Mean (2014) | SD  | Mean (2015) | SD  | Z*  | p   |
|---------------|----|-------------|-----|-------------|-----|-----|-----|
| Study group   | 6  | 12.856      | 6.538| 6.866       | 1.744|     |     |
| Control group**| 2  | 10.885      | 0.162| 8.280       | 1.626|     |     |
| Total         | 8  | 12.364      | 5.601| 7.220       | 1.744| −2.100| .036|

Note. VAP: ventilator-associated pneumonia; ICU: intensive care unit; SD: standard deviation.
*The Wilcoxon test. **Since the diagnostic criteria for VAP changed in 2015 in one ICU in the control group, the data for VAP rate could not be used.

Because there are multiple risk factors leading to VAP and because many factors are closely related to nursing initiatives, the training given to nurses can reduce the incidence of VAP by about 50% [33, 34, 36]. In several studies of the effect of training given to nurses for preventing VAP on the incidence of VAP, it was found that the incidence of VAP was decreased at a statistically significant level [24, 33, 34]. In one study, the effect of training given to ICU staff in short sessions on the VAP rate was a non-significant reduction, but it was suggested that the non-significance may have been due to the lack of infrastructure, such as surveillance monitoring and a very high turnover rate in nurses [23].

In this study, although the VAP rate was lower in the ICUs in the control group than in the ICUs in the study group in 2014, the VAP rate was lower in the ICUs in the study group than in the ICUs in the control group in 2015 (Table 6). One of the VAP preventive/reducing nursing initiatives is the training of the health staff. In this context, awareness is created in nurses through training, and it may therefore be possible to increase the knowledge level of VAP and to implement evidence-based practices. In addition to the study group, the decrease in the incidence of VAP in the control group is also remarkable. One of the important indicators of healthcare quality in ICUs is the incidence of VAP. Therefore, it could be that the study attracted considerable attention in the nurses working in the ICUs. This result suggests that the nurses really responded to the tests with great interest and curiosity. The awareness of the institution of VAP might also have been increased by this study. In this context, it can be considered possible that the institutions developed improved monitoring and applications related to VAP within the year of the study. According to the result obtained from this study, it can be stated that the incidence of VAP in the ICUs can be reduced by providing training to nurses once in every 6 months. This result supports the finding of other studies in which it was reported that the training given to nurses reduced the incidence of VAP. It also confirms our H3 hypothesis.

CONCLUSIONS

Intensive care nurses who are primarily responsible for patient care play an important role in preventing the development of VAP in ICUs. The knowledge and application levels of VAP initiatives and evidence-based strategies for preventing VAP are low for the majority of nurses. This shows that nurses need special training and qualification in ICU nursing. It can be suggested that ICU administrators use a checklist, which includes the Preventive/Reducing Initiatives of VAP, and the practical training of nurses at least every 6 months (to ensure standardized care such as aspiration of subglottic secretions and control of the endotracheal tube cuff pressure) to reduce the incidence of VAP.

Acknowledgements: The authors would like to thank all the intensive care unit workers, especially nurses who participated in this study, and the head nurses who participated in data collection.

Authors’ contribution: HOC contributed to the conception and study design, data collection, data analysis, manuscript preparation, and final approval of the version to be submitted. NK contributed to the study design, data analysis, manuscript preparation, drafting the article, and revising it critically for important intellectual content. The final approved version is submitted.

Ethical approval: The study was approved by the Clinical Research Ethics Committee of Bezmialem Vakif University (Date/Number: 28.11.2014/71306642-050.01.04). Institutional permission was also received from nine hospitals. After the study was completed, the nurses in the control group were also trained.

Conflicts of Interest/Funding: The authors declare no conflicts of interest. No financial support was received for this study.
