Abstract. The paper discusses the problem related to production casing leak repairs in the wells at the sites of PJSC Tatneft. The investigation showed that the most common and frequent problems occurring in the drilling facilities of the company are associated with the Serpukhov-Oka, Famennian and Frasnian stages. It has been found that high fluid loss, or absorption, is the major cause leading to well production string leak. The method of installing a profile liner in the borehole areas with high or complete loss of returns was proposed to prevent production casing string leaks and to improve the string integrity. The new technique involving a profile liner installation contributes considerably to string protection and integrity due to its metal wall thickness and squeeze cementing job quality in the string interval.

1. Introduction
Since most of the Russian oil fields have been explored and large discoveries are occurring less frequently, it is critical for oil producing companies to improve recovery from mature fields at their late stage of development. It is a common knowledge that crude oil reserves in mature fields have very high water cut values. One of the reasons influencing these values is connected with production casing string leaking and repairing, or sealing. Production string leaks may be caused by various criteria, primary cementing operation quality, and well operation peculiarities being the major ones among them. To control and prevent this sort of problem there are various techniques of repairing a leak in a well production string, and they involve using special tools and cementing slurry to improve fluid loss, each having some advantage and disadvantage [1].

2. General Information about the Research
To select a proper method for sealing a leak in the production string successfully it is necessary to study the case. The following data have been determined to start the study: horizons (stages) where the problems occurred more frequently; the number of applied techniques to eliminate the production string problems; satisfactory results of their application achieved in the wells at the sites of Tatneft subdivisions - NGDU Almetyevneft, NGDU Yelkhovneft and NGDU Yamashneft.

The study involved 725 wells; 660 of them have been drilled for the Devonian oil, and 65 wells for the Carboniferous. Horizons and stages of stratigraphic sequence with more frequent problems occurring have been determined, and Fig.1 shows that the most popular in this sense are the Serpukhov-Oka, Famennian and Frasnian stages. These were the stages with complications associated with the absorption of drilling fluid [3.4].
Special attention was paid to out of service wells that had leaks. Wells with complete loss of circulation were compared in relation to the results in their repairing, as they were sealed with the use of profile liner and without using it (different methods). In the intervals with profile liner installed there were no leaks recorded. In the rest of the wells compared, where the problems were caused by intense drilling fluid absorption zone, the leaks were sealed with backfill material. Comparing the wells with and without special liners installed in the same intervals made it possible to prove that the technique is reliable for preventing from aggressive formation fluids and increase the life circle of the well (Fig. 2) [5].
3. Conclusion

Being aware of drilling complications and knowing the intervals where the problems related to partial or complete mud absorption are the most common ones, it is recommended to install a profile liner, and the thickness of its metal wall and better squeeze cementing in this certain interval are able to contribute to improvement of the production casing string reliability. It is a solution to improve well architecture, mitigate drilling hazards, and increase production capacity. After investigating the quality of the cementing job with the use of the relevant profile liner installed and without it we have come to the conclusion that intervals with profile liners had been cemented better, and this leads to significant increase in the lifespan of the well. This can be accounted for the fact that the absorption intervals partially absorb cement as well and this, in turn, causes corrosion of the string, and definitely would have an adverse effect on the integrity of the string.

Using the knowledge gained from multiple successful installations we can state that there are advantages associated with the use of the technology. One of them is the potential to reduce the number of repair works caused by annulus and borehole wall integrity damage, or loss. Moreover, it makes it possible to avoid additional costs for operations undertaken to seal the annulus and provide the well’s integrity.

The technology means that a drilling company does not need to make additional big investments and operational changes when using it in conventional drilling. It is a contingency solution to ensure improvement of the well architecture, though, in some cases, it may be planned beforehand for other reasons. The field experience studied revealed that the wells with the profile liner installed have proved to work successfully several years longer compared to those without of them, and a certain amount of the latter no longer is in operation because of the cementing and integrity loss.
