ABSTRACT. The current work introduces the notion of pdominant sets and studies their recursion-theoretic properties. Here a set $A$ is called pdominant iff there is a partial $A$-recursive function $\psi$ such that for every partial recursive function $\phi$ and almost every $x$ in the domain of $\phi$ there is a $y$ in the domain of $\psi$ with $y \leq x$ and $\psi(y) > \phi(x)$. While there is a full $\Pi_0^1$-class of nonrecursive sets where no set is pdominant, there is no $\Pi_0^1$-class containing only pdominant sets. No weakly 2-generic set is pdominant while there are pdominant 1-generic sets below $K$. The halves of Chaitin's $\Omega$ are pdominant. No set which is low for Martin-Löf random is pdominant. There is a low r.e. set which is pdominant and a high r.e. set which is not pdominant.

1. Introduction

It is known since the beginning of recursion theory that there is a close relation between the computational power of a set $A$ and the classes of recursive and partial recursive functions which can be dominated by an $A$-recursive function \cite{13,14,21}: The halting problem $K$ is Turing reducible to $A$ iff every partial recursive function is majorised by some $A$-recursive total function iff some fixed $A$-recursive function dominates all partial recursive functions. Furthermore, Martin showed that a set $A$ has high Turing degree iff there is an $A$-recursive function $f$ dominating every total recursive function. This generalises to r.e. Turing degrees.
by the fact that an r.e. set $A$ is low$_2$ iff some $K$-recursive function dominates all total $A$-recursive functions.

For r.e. sets, one has also the further result that $A \leq_T B$ iff the convergence module of $A$ is majorised by some $B$-recursive function. It is also known that for sets $A, B \leq_T K$, $A \leq_T B$ iff for every $A$-recursive function $f$ there is a $B$-recursive function $g$ majorising $f$. This does, however, not generalise to the larger class of the sets below $K'$. There is a nonrecursive set $A \leq_T K'$ for which every $A$-recursive function is majorised by a recursive function; such a set $A$ is said to have a hyperimmune-free degree $[16]$.

There have also been various attempts to generalise domination to relations between the partial recursive functions of two relativised worlds. For example, Stephan and Yu [17] considered the notion where $A$ is strongly hyperimmune-free relative to $B$; here $A$ is strongly hyperimmune-free relative to $B$ iff for every partial $A$-recursive function $f$ there is a partial $B$-recursive function $g$ such that $\text{dom}(f) \subseteq \text{dom}(g)$ and $f(x) \leq g(x)$ for all $x \in \text{dom}(f)$. Their results include the result that, when $B \not\geq_T K$ then $A$ is strongly hyperimmune-free relative to $B$ iff $A \leq_T B$. So real power in terms of the degrees of being strongly hyperimmune-free is only achieved by being above $K$. One of the reasons for this phenomenon was that the domains have to be compatible in the sense that whenever $f$ is defined so is $g$ and furthermore $g$ is above $f$.

The notion investigated in the current work tries to overcome this shortcoming by permitting $g$ to be above the value $f(x)$ not at $x$ itself but at places below $x$. In this initial work, the emphasis is more on domination than majorisation; that is, on the question of when there is a partial $B$-recursive function dominating all partial $A$-recursive functions in this sense. Then $B$ must be properly above $A$ and already the question when this can be done with the lower oracle being recursive turned out to be an interesting and challenging notion.

The notion itself stems from a principle in reverse mathematics, more precisely, it is motivated by the bounded monotone enumeration principle BME. Chong, Slaman and Yang [13] introduced BME in order to analyse the rate of growth of a finite collection of partial recursive functions in a nonstandard model of a fragment of Peano arithmetic. The ability to control the growth rate in that model was key to separating stable Ramsey’s theorem for pairs from Ramsey’s theorem for pairs over the system RCA$_0$.

The formal definition of when a function pdominates another function or a set of functions is the following.

**Definition 1.1.** If $\psi$ and $\phi$ are partial functions, $\psi$ pdominates $\phi$ iff for almost all $x \in \text{dom}(\phi)$ there is a $y \in \text{dom}(\psi)$ with $y \leq x$ and $\psi(y) > \phi(x)$; $\psi$ pdominates a set of partial functions iff it pdominates every partial function in it. A set $A$ is pdominant iff some partial $A$-recursive function pdominates the set of all partial recursive functions.

This property can indeed be formulated in a stricter way and therefore the following equivalent property turned out to be fruitful for various proofs.

**Proposition 1.2.** A set $A$ is pdominant iff there is a partial $A$-recursive function $\psi$ such that for all constants $k$ and all partial recursive functions $\phi$ and almost all $x \in \text{dom}(\phi)$ there is a $y \in \text{dom}(\psi)$ with $y \leq x/k$ and $\psi(y) > \phi(x)$.

**Proof.** Given $\psi$ and a partial recursive function $\phi$ and a constant $k$, consider the functions $\phi_\ell$ given by $\phi_\ell(x) = \phi(kx + \ell)$. For each $\ell$ and almost all $x$ in the domain of $\phi_\ell$ there is a $y \leq x$ in the domain of $\psi$ with $\psi(y) > \phi_\ell(x)$. It follows that for almost all $x$ in the domain of $\phi$ there is a $y \leq x/k$ in the domain of $\psi$ with $\psi(y) > \phi(x)$. \qed
Clearly the sets above the halting problem $K$ are pdominant. One might ask whether there are natural examples of sets which are pdominant but not above the halting problem. Indeed, taking the half of Chaitin’s $\Omega$ [2, 3] provides such an example. Martin-Löf random sets [15] are those sets $A$ for which there is not a uniformly r.e. sequence of open classes $C_0, C_1, \ldots$ such that $\mu(C_n) < 2^{-n} \land A \in C_n$ for all $n$.

**Example 1.** Let $\Omega$ be a left-r.e. Martin-Löf random set and $A$ be given by $A(n) = \Omega(2n)$. Then $A$ is low and $A$ is pdominant.

*Proof.* The lowness of $A$ is well-known [18, Corollary 3.4.11]. Now it is shown that $A$ is pdominant. Let $\Omega_s$ be an approximation of $\Omega$ from the left. On input $x = 2^n + \sum_{m<n} 2^m \cdot a_m$, let $\psi^A(x)$ be the first stage $s$ such that $\Omega_s(0)\Omega_s(1)\ldots\Omega_s(2n) = A(0)a_0A(1)a_1\ldots A(n-1)a_{n-1}A(n)$. The function $\psi^A$ is partial recursive and in the case that $x = 2^n + \sum_{m<n} 2^m \cdot \Omega(2m+1)$, $\psi^A(x)$ is the time to approximate the string $\Omega(0)\Omega(1)\ldots\Omega(2n)$ from the left. Assume now by way of contradiction that there would be a partial recursive function $\phi$ such that for infinitely many $x$ in the domain of $\phi$ there is no $y \leq x$ with $\psi^A(y) > \phi(x)$. Taking now $n$ such that $2^{n+1} \leq x < 2^{n+2}$ for such an $x$, it would follow that $s = \phi(x)$ satisfies $\Omega_s(m) = \Omega(m)$ for $m = 0, 1, \ldots, 2n$. So one could compute $\Omega$ up to $2n$ for infinitely many $n$ from an input to $\phi$ which has $n+1$ binary bits. Hence, for infinitely many $n$ it would hold that $C(\Omega(0)\Omega(1)\ldots\Omega(2n)) \leq n+c$ for some constant $c$ in contradiction to the fact that $\Omega$ is Martin-Löf random.

Note that in a similar spirit, one can show the following property: If $A$ is a set which is Martin-Löf random relative to $\Omega$, then $\Omega$ is also Martin-Löf random relative to $A$ and therefore the convergence module $c_\Omega$ of $\Omega$ is a total function which pdominates the set of all partial $A$-recursive functions. Thus, if one relativises the notion, one can have two oracles, namely $A$ and $\Omega$, such that a total $\Omega$-recursive function dominates all partial $A$-recursive functions though $A \not\leq_T \Omega$.

For further properties of $\Omega$, see the usual textbooks on Kolmogorov complexity and recursion theory [5, 12, 18, 19, 22, 23]. In the following sections, it will be investigated which types of sets can be pdominant and which not. The first results will deal with $\Pi^0_1$ classes which are a convenient tool to construct sets of various types; for the construction of pdominant sets, they turn out to be of limited value as no $\Pi^0_1$ class consists entirely of pdominant sets and some do not contain any pdominant set.

## 2. $\Pi^0_1$-classes and pdominance

For the purposes of this paper, $\Pi^0_1$-classes are classes of sets represented by their $\{0, 1\}$-valued characteristic functions and they are not empty. Furthermore, a $\Pi^0_1$-class is called nonrecursive iff it contains only nonrecursive sets. $\Pi^0_1$-classes correspond to the sets of infinite branches of recursive trees.

**Theorem 2.1.** Every $\Pi^0_1$-class contains a set which is not pdominant.

*Proof.* Let a $\Pi^0_1$-class be given as the infinite branches of a recursive tree $T_0$. Now one defines inductively a sequence of trees $T_1, T_2, \ldots$ such that the following holds for all trees:

- $T_0 \supseteq T_1 \supseteq T_2 \supseteq \ldots$;
Theorem 2.2. There is a nonrecursive $A$ such that the Cantor Space. Let $A$ and the intersection of a descending intersection of nonempty compact sets is not empty in $A$. Note that the intersection of a descending sequence of binary trees with infinite branches is not empty, as each tree defines a compact subset of the set of possible infinite branches and the intersection of a descending intersection of nonempty compact sets is not empty in the Cantor Space. Let $A$ be an infinite branch which is on all trees $T_e$.

Now consider the following function $\psi$: The algorithm for $\psi(x)$ searches first for numbers $a, e, b$ with $x = 2^{(a, e)} + b$ and $b < 2^{(a, e)}$ If these numbers can be found, then the algorithm goes on with determining for each set $B$ the first number $t$ found such that either $B(0)B(1)\ldots B(t)$ is not on the tree given by $\varphi_a$ or there are $b$ distinct numbers $u_1, u_2, \ldots, u_b \leq 2^{(a, e)} - 2$ satisfying for each $y \in \{u_1, u_2, \ldots, u_b\}$ that $\varphi^e_{a,t}$ is defined and below $t$. In the case that these searches terminate for all oracles $B$, for compactness reasons, the algorithm can find a uniform proper upper bound $t'$ on all these $t$ and it then outputs this $t$.

Assuming now by a way of contradiction that $\psi$ is the partial function witnessing that $A$ is pdominant. Then there are infinitely many $e$ such that $\varphi^A_e = \psi$. For each such $e$ and the corresponding $a, b$ it holds that (a) $\varphi^A_e$ is defined on $b$ places below $2^{(a, e)} - 2$ for all infinite branches of $T_e$ and (b) $\psi(2^{(a, e)} + b)$ returns a value $t'$ which is larger than $\psi(y)$ for all $y$ in the domain of $\psi$ satisfying $y \leq 2^{(a, e)} - 2$; these $y$ contain every $y \in \text{dom}(\psi)$ with $y \leq (2^{(a, e)} + b)/8$. Hence the function $\psi$ does not witness in sense of Proposition 1.2 that $A$ is pdominant. As the choice of $\psi$ was arbitrary, it follows that $A$ is not pdominant. □

Theorem 2.2. There is a nonrecursive $\Pi_1^0$-class not containing any pdominant set.

Proof. The idea is to construct a partial recursive $\{0, 1\}$-valued function $\vartheta$ and let the $\Pi_1^0$-class be the class of all total extensions. At each stage $s$, let $a_{m,s}$ be the $m$-th non-element of the domain of $\vartheta$. Now one updates $\vartheta$ according to that of the following actions which has highest priority, that is, the lowest parameter $m$ being involved.

- If $\varphi_{m,s}$ and $\vartheta_s$ are consistent, that is, not different in the common domain, and if $\varphi_{m,s}(a_{m,s})$ is defined, then make $\vartheta_{s+1}(a_{m,s})$ be defined and different from $\varphi_{m,s}(a_{m,s})$.
- If there is a string $\tau \in \{0, 1\}^s$ consistent with $\vartheta_{m,s}$ and the value $u = \langle m, a_{0,s}, \tau(a_{0,s}), a_{1,s}, \tau(a_{1,s}), \ldots, a_{m,s}, \tau(a_{m,s}) \rangle$ does not satisfy that $\varphi^\tau_{\vartheta_{s+1}}(y) \downarrow \varphi^\tau_{\vartheta_{s+1}}(y) \downarrow$ for all $e, y \leq 2u - 2$ then let $\vartheta_{s+1}(z) = \tau(z)$ for $z = a_{m,s} + 1, a_{m,s} + 2, \ldots, s - 1$.

Here it is assumed that at any pairing of finitely many coordinates the formed pair is larger than every single coordinate. Note that the requirements are set up in a way that it happens only at finitely many stages that $\vartheta_{s+1}(a_{m,s})$ becomes defined, hence for each $m$ the limit $a_m$ of the $a_{m,s}$ exists and is outside the domain of $\vartheta$. By the first of the two requirement for $m$, every member of the resulting $\Pi_1^0$-class will be different from $\varphi_m$ whenever the latter is total. So the resulting $\Pi_1^0$-class is nonrecursive.

Now assume by way of contradiction that $A$ is in the resulting $\Pi_1^0$-class and that $\psi = \varphi^A_e$ witnesses that $A$ is pdominant. Then there is, for each $m > e$, a value $u$ of the form $u = \langle m, a_0, A(a_0), a_1, A(a_1), \ldots, a_m, A(a_m) \rangle$. 
Let $b$ be the number of places $y$ such that $\varphi_s^A(y)$ is defined below $2^{u-2}$. Now one can define a partial recursive function $\phi$ such that whenever $x = 2^u + b$ for $u, b$ as above then $\psi(x)$ decodes $m, a_0, a_1, \ldots, a_m, A(a_0), A(a_1), \ldots, A(a_m)$ from $u$ and waits until an $s$ is found such that $a_{k,s} = a_k$ for $k \leq m$ and there are $b$ values $y \leq 2^{u-2}$ for which $\varphi_{e,a_{m+1},s}^A(y)$ is defined and is below $s$. Then $\phi(x)$ takes the value $s + 1$.

One can easily verify that whenever the parameters $e, b$ are taken as above, all the involved computations halt and the corresponding $s$ is found and the value $s + 1$ returned is strictly larger than $\psi(y)$ for all $y \leq x/8$ which are in the domain of $\psi$. Hence, by Proposition 1.2, $A$ cannot be pdominant in contradiction to the assumption. In other words, no member $A$ of the constructed $\Pi_1^0$-class is pdominant.

Remark 2.3. One can construct a $\Pi_1^0$-class with one nonrecursive branch of the same Turing degree as $K$ and some recursive branches. Hence there is a nontrivial $\Pi_1^0$-class where all nonrecursive members are pdominant.

3. Pdominant Sets and Genericity

An extension function $F$ is a partial function which on input $\sigma$ is either undefined or maps $\sigma$ to a string extending $\sigma$. A set $A$ meets an extension function $F$ iff there is an $n$ such that either $F(A(0)A(1)\ldots A(n)\sigma)$ is undefined for all $\sigma$ or $F(A(0)A(1)\ldots A(n)) = A(0)A(1)\ldots A(m)$ for some $m \geq n$.

A set $A$ is called 1-generic iff it meets every partial recursive extension function; a set $A$ is called weakly 2-generic iff it meets every total $K$-recursive extension function.

Note that every weakly 2-generic set meets each total $K$-recursive extension function infinitely often in the sense that for every such $F$ there are infinitely many $n$ with $F(A(0)A(1)\ldots A(n))$ being a prefix of $A$.

The 1-generic sets are used implicitly in Friedberg’s Jump Inversion theorem, see [6]. Jockusch [9, 10] formally introduced 1-generic sets and its variants.

Theorem 3.1. No weakly 2-generic set is pdominant.

Proof. Let $A$ be a weakly 2-generic set. Assume by way of contradiction that $A$ is pdominant and that the partial $A$-recursive function $\psi^A$ with oracle $A$ witnesses this fact.

Define a partial recursive extension function $\gamma$ such that $\gamma(\sigma, u)$ is the length-lexicographically first extension $\tau$ of $\sigma$ such that there is an $x \leq u$ for which $\psi^A_{\tau|\sigma}(x)$ is defined while $\psi^A_{\tau|\sigma}(x)$ is undefined. $\Gamma(\sigma, u)$ is obtained by iterating $\gamma$ as long as possible: $\Gamma(\sigma, u) = \sigma_n$ for the largest $n$ where $\sigma_n$ is defined where inductively $\sigma_0 = \sigma$ and $\sigma_{m+1} = \gamma(\sigma_m, e, u)$ whenever that is defined. Note that $\gamma$ is partial recursive and that $\gamma_{u+2}$ cannot exist as for each $m$ where $\sigma_{m+1}$ is defined there is at least one $x_m \leq u$ with $\psi^A_{\tau|\sigma}(x_m)$ being defined iff $\sigma_k$ exists and $k \geq m + 1$. Hence $\Gamma$ is a total $K$-recursive function.

Now one considers the extension function which maps $\sigma$ to $\Gamma(\sigma, 2^{n_0(\sigma)})$ where $n_0$ is a recursive bijection from strings to natural numbers.

There are infinitely many prefixes $\sigma_0$ of $A$ such that $\Gamma(\sigma_0, 2^{n_0(\sigma_0)} - 2)$ is a prefix of $A$ as well. For any such prefix $\sigma_0$, let $c = n_0(\sigma_0) - 2$ and let $n$ be the maximal number such that $\sigma_n$ is defined where $\sigma_{m+1} = \gamma(\sigma_m, 2^{c-2})$ whenever $\sigma_m$ is defined and $\gamma(\sigma_m, 2^{c-1})$ is defined.

Let $\phi(2^c + n)$ be the partial recursive function which computes $c, n, \sigma_0$ from $2^c + n$, computes $\sigma_n$ from $\sigma_0$ through $n$ times iterating $\gamma$ with the corresponding inputs and then
outputs
\[ 1 + \max\{\psi_{\sigma_n}^\sigma(x) : x \in \text{dom}(\psi_{\sigma_n}^\sigma) \land x \leq 2^{c-2}\}. \]

One can now easily see that \( \phi(2^n + n) > \psi(y) \) for all \( y \leq 2^{c-2} \) in the domain of \( \psi \) in the case that \( \sigma_0, \Gamma(\sigma_0, 2^{\alpha(\sigma_0) - 2}) \) are both prefixes of \( A \) and \( n \) is the number of extensions such that \( \sigma_n = \Gamma(\sigma_0) \). So, for the constant \( k = 8 \) and the infinitely many \( x \) of the form \( 2^n + n \) in the domain of \( \phi \) with \( n, c \) derived from the corresponding \( \sigma_0 \) there is no \( y \leq x/8 \) in the domain of \( \psi \) with \( \psi(y) > \phi(x) \). Hence \( A \) is not pdominant.

**Theorem 3.2.** There is a pdominant 1-generic set.

**Proof.** The idea is to construct the 1-generic set \( A \) as a sequence \( \sigma_0\tau_0\sigma_1\tau_1 \ldots \) such that the \( \sigma_n \) is chosen such that the \( n \)-th 1-genericity requirement is satisfied and \( \tau_n \) contains information about the halting problem \( K \) which is sufficient to permit partial domination. More precisely, \( \sigma_n \) is the first string found such that \( \sigma_0\tau_0\sigma_1\tau_1 \ldots \sigma_n-1\tau_n-1\sigma_n \) is enumerated into the \( n \)-th r.e. set of strings; if no such string is found then one takes \( \sigma_n \) to be the empty string. These enumeration procedures are fixed from now on, so that the coding and decoding always refers to the same way of enumerating the \( n \)-th r.e. set. The string \( \tau_n \) encodes whether \( \varphi_e(x) \) halts for all \( e, x < 2^{n+3} \): So \( \tau_n \) has length \( 4^{n+3} \) and for all \( e, x < 2^{n+3} \), if \( \varphi_e(x) \) halts then \( \tau_n(2^{n+3}e + x) = 1 \) else \( \tau_n(2^{n+3}e + x) = 0 \).

Now one can construct the following function \( \psi^A \) using the algorithm below which is undefined whenever some of the computations on the way are not terminating:

- On input \( y \), determine \( n, a_0, \ldots, a_n \) such that \( y = 2^{n+1} + \sum_{m \leq n} 2^m a_m \).
- For \( m = 0, 1, \ldots, n \): if \( a_m = 1 \) then search for the first \( \sigma_m \) found such that the string \( \sigma_0\tau_0\sigma_1\tau_1 \ldots \sigma_{m-1}\tau_{m-1}\sigma_m \) is enumerated into the \( n \)-th r.e. set else let \( \sigma_m \) be the empty string; let \( \tau_m \) be that string of length \( 4^{m+5} \) which makes \( \sigma_0\tau_0\sigma_1\tau_1 \ldots \sigma_m\tau_m \) to be a prefix of \( A \). If either the search does not terminate or the prefix-condition cannot be satisfied then \( \psi^A(y) \) is undefined.
- Having \( \tau_n \), one simulates all computations \( \varphi_e(x) \) with \( e, x < 2^{n+3} \) and \( \tau_n(2^{n+3}e + x) = 1 \) until they terminate with a value \( z \). If all these simulations terminate then \( \psi^A(y) \) is \( z + 1 \) for the largest \( z \) returned in these simulations else \( \psi^A(y) \) is undefined.

If now \( \varphi_e(x) \) is defined, \( n > e \) and \( 2^{n+2} < x < 2^{n+3} \) then one can choose \( a_0, a_1, \ldots, a_n \) such that \( a_m = 1 \) whenever the search for \( \sigma_m \) finds this string and \( a_m = 0 \) otherwise. Now considering \( y = 2^{n+1} + \sum_{m \leq n} 2^m a_m \), \( \psi^A(y) \) is defined, \( \psi^A(y) > \varphi_e(x) \) and \( y < x \). Hence \( A \) is pdominant. \[ \square \]

Note that the 1-generic set constructed is actually below \( K \). Theorem 1.1 below shows that there are also 1-generic sets below \( K \) which are not pdominant; this holds as there are 1-generic sets which are low for Martin-Löf random.

4. Pdominance and lowness

As mentioned in the introduction, a pdominant set \( A \) can be low, that is, satisfy \( A' \leq_T K \).

Furthermore, it can even be superlow, as one can construct the sequence of the \( \sigma_n \) and \( \tau_n \) relative to Theorem 3.2 such that the \( \sigma_n \) is not taken to satisfy a 1-genericity requirement but to fix the \( n \)-th bit in the jump of \( A \). Indeed, one can for each \( n \) ask how often approximations to the sequence of the \( \sigma_0\tau_0\sigma_1\tau_1 \ldots \sigma_n\tau_n \) changes where each change is either caused by some bit in some \( \tau_m \) going from 0 to 1 or by finding a \( \sigma_m \); the latter can
be undone later if some $\sigma_k$ is found with $k < m$ or some bit is enumerated into a $\tau_k$ with $k < m$. Nevertheless, one can compute from $n$ an upper bound on the number of changes and a truth-table query to $K$ permits then to get the amount of actual changes. Hence $A'$ is truth-table reducible to $K$.

So the next step in making pdominant sets to be even lower than superlow would be to make them low for Martin-Löf random. But that goal can no longer be achieved as the following result shows.

**Theorem 4.1.** Let $A$ be a pdominant set. Then $A$ is not low for Martin-Löf randomness.

**Proof.** Recall that $H$ denotes the prefix-free Kolmogorov complexity $\overline{1}$. First, it is well-known that one can choose the universal machine $U$ such that there is a recursive approximation $H_t$ of $H$ from above satisfying for infinitely many $x$ that $H(x) = H_0(x)$. In other words, the first approximation $H_0$ is a Solovay function for $H$ $\overline{4}$ Proof of Proposition 2.5.

Second, for each $x$ let $s(x, c)$ denote the number of strings $y$ which are of length $x$ such that $H(y) < x + H_0(x) - c$. Fix the value $c$ such that there are infinitely many $x$ with $H(x) = H_0(x)$ and $s(x, c) < 2^x$: This value exists, since there is a constant $c'$ with

$$\sum_{y \in \{0, 1\}^x} 2^{-H(y)} > 2^{-c' - H(x)} \text{ and } \forall y \in \{0, 1\}^x [H(y) < H(x) + c'].$$

The assumption $H(y) < x + H_0(x) - c'$ for all $y$ of length $x$ implies that

$$\sum_{y \in \{0, 1\}^x} 2^{-H(y)} \leq \sum_{y \in \{0, 1\}^x} 2^{-x - H_0(x) - c'} \leq 2^{-c'H_0(x)}$$

and thus $H(x) < H_0(x)$. It follows that any $c > c'$ is a reasonable choice to satisfy the condition, so let $c = c' + 2$. For this $c$, there is furthermore a minimal constant $d$ such that $s(x, c) \geq 2^{x-d}$ for infinitely many $x$ satisfying $H(x) = H_0(x)$ and $s(x, c) < 2^x$: As mentioned, all strings $y$ of length $x$ satisfy $H(y) \leq H(x) + c'$. Thus there is a constant $c''$ such that for all $d'$, $2^{x-2d'}$ of these strings $y$ satisfy $H(y) \leq H_0(x) + x + c'' - d'$. From this fact, one can conclude the existence of some $d$ with the desired properties and then take the minimal one among the possible values. Let

$$B = \{x : H(x) = H_0(x) \land 2^{x-d} \leq s(x, c) < 2^{x-(d-1)}\}$$

be the infinite set of these $x$.

Third, by Proposition $\overline{1.2}$, $\psi^A$ is a partial $A$-recursive function such that for all $\varphi_e$, all $k$ and almost all $a \in dom(\varphi_e)$ there is a $b \in dom(\psi^A)$ with $b \leq a \cdot 2^{-2k-1} \land \psi^A(b) > \varphi_e(a)$.

Fourth, now let $\varphi_e$ be the function which on input $a$ computes first the integer $x$ with $2^{x-d} \leq a < 2^{x-(d-1)}$ and then searches for the first $t$ such that there are $a$ distinct strings $y \in \{0, 1\}^x$ with $H_t(y) < x + H_0(x) - c$. Note that for all $x \in B$ the value $\varphi_e(s(x, c))$ is defined and returns the time $t$ which is needed until all strings $y \in \{0, 1\}^x$ with $H(y) < x + H_0(x) - c$ indeed satisfy $H_t(y) < x + H_0(x) - c$. For each number $k$ and almost all $x \in B$ there is a $b \leq a \cdot 2^{-2k-1}$ with $\psi^A(b) > \varphi_e(s(x, c))$; note that $b \leq a \cdot 2^{-2k-1}$ implies $b < 2^{x-2k-1}$.

Fifth, consider any $x$ and let $p$ be any program for the universal machine on which $H$ is based with output $x$. Now one makes a prefix-free machine $M^A$ which takes inputs of the form $p \cdot 0^k 1 \cdot z$ where $p$ is in the domain of the prefix-free universal machine and the length of $z$ is $x - 2k - 1$ provided that the prefix-free universal machine outputs $x$ on input $p$. On inputs of these form, $M^A$ finds $p$ and determines $x$, then $M^A$ determines the binary value $b$ of $z$ and then $M^A$ runs the computation $t = \psi^A(b)$. If all these computations halt then
$M^A$ outputs the lexicographic first string $y \in \{0,1\}^x$ with $H_t(y) \geq x + |p| - c$ (provided that this exists).

Sixth, in the case that $x \in B$ and $p$ is a shortest program for $x$ in the universal machine and $\psi^A(b) > \varphi_e(s(x,c))$ for some $b < 2^{x-2k-1}$ and $z$ coding $b$ in $x - 2k - 1$ binary bits, $M^A(p \cdot 0^k 1 \cdot z)$ returns a string $y$ with $H(y) \geq x + H(x) - c$. Furthermore, the input for $M^A$ to generate $y$ is of length $|p| + x - k$ where $|p| = H(x)$. It follows that there is for each $k$ a string $y$ such that the partial $A$-recursive machine $M^A$ generates $y$ from a string which is $k - c$ bits shorter than its unrelativised Kolmogorov complexity. Hence $A$ is not low for prefix-free Kolmogorov complexity and thus $A$ is also not low for Martin-Löf randomness.\]

The last result showed that every set which is low for Martin-Löf random cannot be pdominant. As there are sets of nonrecursive r.e. degree, sets of minimal Turing degree and 1-generic sets which are all low for Martin-Löf random, one gets by this result alternative proofs to the preceding ones that sets of those types might not be pdominant.

One generalisation of sets which are low for Martin-Löf random are those which are low for $\Omega$. Therefore the following question is natural.

**Open Problem 4.2.** Is there a pdominant set which is low for $\Omega$?

Furthermore, one might also like to know whether a further lowness notion is compatible with pdominance.

**Open Problem 4.3.** Is there a pdominant set of hyperimmune-free Turing degree?

## 5. R.e. sets and pdominance

In this section it is shown that pdominant sets are orthogonal to the low-high-hierarchy. That is, there is a low r.e. set which is pdominant and a high r.e. set which is not pdominant.

**Theorem 5.1.** There is a low r.e. set which is pdominant.

**Proof.** The idea would be to construct in the limit a set $A$ such that its characteristic function consists of a sequence $\sigma_0 \tau_0 \sigma_1 \tau_1 \ldots$ where each $\sigma_n$ can become longer over time and each $\tau_n$ has the length $2^{n+3}$. As in Theorem 3.2, $\tau_n(2^{n+3}e + x) = 1$ if $\varphi_e(x)$ halts and $\tau_n(2^{n+3}e + x) = 0$ if $\varphi_e(x)$ does not halt for all $e, x < 2^{n+3}$. Furthermore, the $\sigma_n$ can be made longer and takes then the current values of $A_s$ at the corresponding positions, that is, increasing the length of $\sigma_n$ does never change the values of $A_s$. Whenever an interval $\sigma_n$ becomes longer than it is made to extend up to $s$ and the strings $\tau_n, \sigma_{n+1}, \ldots$ keep their length but have all bits reset to 0, as $A_s$ does not contain elements beyond $s$. The algorithm is now the following:

- Identify the first string $\sigma_n$ or $\tau_n$ in the characteristic function which needs attention.
- Here $\sigma_n$ occupying an interval from $i$ to $j$ with $j < s$ needs attention when $\varphi^{A_j}_n(n)$ converges but needs more than $j$ and less than $s$ steps. If $\sigma_n$ receives attention then $\sigma_n$ is adjusted to cover the interval from $i$ to $s$ and $A_{s+1} = A_s$, that is, $\sigma_n$ takes the value $A_e(i) \ldots A_e(s)$. Each of the strings $\tau_n, \sigma_{n+1}, \sigma_{n+2}, \ldots$ keeps its length but has its values set to 0, so if $\tau_{n+1}$ was $b_1 b_2 \ldots b_k$ for some $k$ then its new value is $0^k$.
- Here $\tau_n$ occupying an interval from $i$ to $j$ with $j < s$ needs attention when $\tau_n(2^{n+3}e + x) = 0$ and $\varphi_e(x)$ converges within $s$ computational steps. If $\tau_n$ receives attention then $i + 2^{n+3}e + x$ is put into $A_{s+1}$ and thus $\tau_n(2^{n+3}e + x)$ becomes 1. Moreover, if $\sigma_{n+1}$
We make the assumption that for any oracle $X$ there is a high r.e. set which is not pdominant. This permits to conclude that the strings $R_2, R_3, \ldots$ keeps its length but has its values reset to 0, so if $\tau_{n+1}$ was $b_1 b_2 \ldots b_k$ for some $k$ then its new value is $0^k$.

Note that when $\sigma_0, \tau_0, \sigma_1, \tau_1, \ldots, \sigma_{n-1}, \tau_{n-1}$ have found their final values then $\sigma_n$ will receive attention at most once in order to change $A'(n)$ from 0 to 1; afterwards $\tau_n$ might receive attention up to $4^{n+3}$ times as each of its bits can go from 0 to 1.

Note that $A'(n)$ can only change from 1 to 0 when some string of priority higher than $\sigma_n$ receives attention or when the right end of $\sigma_n$ is beyond $s$. This happens only finitely often and so $A$ is low.

Now define $\psi^A(y)$ as follows. Determine $n, a_0, a_1, \ldots, a_n$ such that $y = 2^{n+1} + \sum_{m \leq n} 2^m \cdot a_m$ (if these values exist). Now find the first $s$ such that, inductively, the following holds for all $m = 0, 1, \ldots, n$: $\sigma_m$ has received exactly $a_m$ times attention after the last time that some interval before $\sigma_m$ has received attention; the string $\sigma_0 \tau_0 \sigma_1 \tau_1 \ldots \sigma_n \tau_n$ is a prefix of $A$. If a stage $s$ is found, then simulate all computations $\psi_e(x)$ with $e, x < 2^{n+3}$ until they deliver an output $z$ and return the least proper upper bound of these values $z$.

Now consider any $\psi_e$ and any $n, x$ with $e < n$ and $2^{n+2} \leq x < 2^{n+3}$. Furthermore, choose $a_0, a_1, \ldots, a_n$ such that $a_m = 1$ iff in the construction $\sigma_m$ has received attention after all the higher priority strings $\sigma_0, \tau_0, \sigma_1, \tau_1, \ldots, \sigma_{n-1}, \tau_{n-1}$ have received attention for the last time. Then, in the above definition, $\psi^A(y)$ with $y = 2^{n+1} + \sum_{m \leq n} 2^m \cdot a_m$ is defined and is a proper upper bound of $\psi_e(x)$ whenever the latter is defined. This witnesses that $A$ is pdominant.

**Remark 5.2.** Actually one can show in Theorem 5.3 that $A$ is even superlow. This is done by observing that a string $\sigma_n$ receives attention at most once in any interval of time where no higher priority string receives attention. Furthermore, $\tau_n$ receives attention at most $4^{n+3}$ times during any interval of time where no higher priority string receives attention. This permits to conclude that the strings $\sigma_0, \tau_0, \sigma_1, \tau_1, \ldots, \sigma_n, \tau_n$ altogether receive at most $2^{n+1} \cdot 5^3 \cdot 5^4 \cdot 5^5 \cdot \ldots \cdot 5^{n+3}$ times attention. One can therefore find out with a tt-reduction to $K$ how often these intervals receive attention and then simulate the construction until that attention was granted for the last time and then one knows whether $A'(n)$ holds or not. So $A' \leq_{wtt} K$ and indeed $A' \leq_{tt} K$ as wtt-reductions to $K$ can be turned into tt-reductions. It follows that $A$ is superlow.

**Theorem 5.3.** There is a high r.e. set which is not pdominant.

**Proof.** Let $\langle \phi_e \rangle_{e \in \omega}$ be an effective listing of all partial recursive functions, and let $\langle \Psi_e \rangle_{e \in \omega}$ be an effective listing of all Turing functionals. We let $\psi_e$ denote the use functional of $\Psi_e$. We make the assumption that for any oracle $X$, if $\Psi_e^X(y)$ converges at stage $s$, then both $y$ and $\psi_e^X(y)$ are less than $s$.

We build an r.e. set $A$, an $A$-recursive function $\Gamma^A$, and partial recursive functions $\langle f_0^e \rangle_{e \in \omega}$ and $\langle f_1^e \rangle_{e \in \omega}$ meeting the following requirements:

1. $G$: $\Gamma^A$ is total.
2. $P_e$: If $\phi_e$ is total, $\Gamma^A$ dominates $\phi_e$.
3. $R_e$: $\Psi_e^A$ fails to pdominate at least one of $f_0^e$ and $f_1^e$.

$G$ with the $P_e$’s guarantees that $A$ is high, while the $R_e$’s ensure that $A$ is not pdominant. The $R_e$-requirement will not be met directly, but will instead be met through subrequirements:
We can take this as our definition of $\gamma$.

Clearly if infinitely many of these subrequirements are met, the $R_e$-requirement will be met.

Our strategy for meeting an $R_{e,n}$-requirement will involve guessing which of the $\phi_{e'}$ are total, which we accomplish via a tree of strategies. We define the tree by devoting all nodes at level $2e$ to the $P_e$-requirement, and all nodes at level $2(e,n)+1$ to the $R_{e,n}$-requirement.

The global $G$-requirement does not appear on the tree.

Nodes devoted to a $P_e$-requirement have two possible outcomes, $\text{inf}$ and $\text{fin}$ (denoting whether or not $\phi_e$ is total). All other nodes have only one possible outcome, which we will simply call outcome. Thus we can define the tree of strategies recursively: the empty string $\langle \rangle$ is the root of the tree; if $\sigma$ is on the tree at level $2e$, then $\sigma_{\text{inf}}$ and $\sigma_{\text{fin}}$ are its two children; if $\sigma$ is on the tree at level $2(e,n)+1$, then $\sigma_{\text{outcome}}$ is its unique child.

If $\tau_0$ and $\tau_1$ are nodes on the tree, we say that $\tau_0$ is to the left of $\tau_1$ if there is a node $\sigma$ on the tree with $\sigma_{\text{inf}} \subseteq \tau_0$ and $\sigma_{\text{fin}} \subseteq \tau_1$. It is simple to verify that this is a transitive relation.

For a node $\sigma$, accessible at stage $s$ and of length $\leq s$, we describe what actions $\sigma$ takes at stage $s$, and if $|\sigma| < s$, which outcome of $\sigma$ is next accessible. We also describe the action of the $G$-strategy.

**Strategy for meeting the $G$-requirement.** We partition $\omega$ in some effective fashion as $\omega = \{\langle e, x \rangle \mid e < x \}$ with $\langle e, x \rangle < \langle e, x' \rangle$ whenever $x < x'$. At stage $s$, for every $x < s$, if $\Gamma_s^A(x)[s]$ is not defined, we define

$$\Gamma_s^A(x)[s] = \max\{\phi_{e,s}(x) \mid e < x \land \phi_{e,s}(x)\}$$

with use $\gamma_s^A(x)[s] = \max\{\langle e, x \rangle \mid e < x\} + 1$.

**Strategy for meeting the $P_e$-requirement.** Whenever this strategy is initialised, we choose a threshold $m$. It suffices to let $m$ be the stage at which the strategy was initialised.

Let $\ell_s(e)$ be largest such that $\phi_{e,s} |_{\ell_s(e)}$ converges.

At stage $s$, consider all $x < \ell_s(e)$. If $\langle e, x \rangle > m$, we enumerate $\langle e, x \rangle$ into $A$. After considering all such $x$, we pass to the next accessible node.

Let $t < s$ be the last stage at which $\sigma_{\text{inf}}$ was accessible ($t = 0$ if there is no such stage). If $\ell_t(e) < \ell_s(e)$, we let $\sigma_{\text{inf}}$ be accessible and initialise all strategies $\tau \supseteq \sigma_{\text{fin}}$. Otherwise, we let $\sigma_{\text{fin}}$ be accessible.

**Strategy for meeting the $R_{e,n}$-requirement.** When $\sigma$ is initialised, it will claim an interval of the form $[k, 3k]$ on which it will define $f_0^e$ and $f_1^e$. We must have $k > n$, and the interval must be disjoint from any interval previously claimed by any $R_{e',n'}$-requirement. We can take this as our definition of $k$: $k$ is the least number greater than $n$ with $[k, 3k]$ disjoint from every interval previously claimed by any $R_{e',n'}$-requirement. Since only finitely many intervals can have been claimed by any stage, there will always be such a $k$. At a stage $s$ when $\sigma$ is accessible, let

$$b = \min\{\langle e', \ell_s(e') \rangle \mid \tau_{\text{inf}} \subseteq \sigma \text{ for some } P_{e'}\text{-strategy } \tau\};$$

$$p = \max\{\Psi_s^A(y)[s] \mid y \in \text{dom } \Psi_s^A[s] \land y \leq 3k \land \psi_s^A(y)[s] < b\};$$

$$q = \max\{f_{e,s}^i(x) \mid i < 2 \land k \leq x \leq 3k \land x \in \text{dom } f_{e,s}^i\}.$$
Verification. We define the true path of the construction recursively. The empty string which

Claim 5.4. If \( e \) is accessible at infinitely many stages.

\( P \) is accessible at stage \( s \).

Fix \( \tau \), then \( \sigma \) is initialised at this stage, including \( \tau \) if \( \sigma \) is on the true path. Then \( \sigma \) is the next accessible node until we reach a node of length \( s \). Once we have acted according to the strategy for the node of length \( s \), we let the \( G \)-strategy act and then proceed to stage \( s + 1 \).

Construction. We begin stage \( s \) by letting \( \langle \rangle \) be accessible and acting according to its described strategy. This strategy determines one of its children to be the next accessible node, which then acts according to its strategy. We continue in this fashion, letting each accessible node choose one of its children to be the next accessible node until we reach a node of length \( s \). Since we have acted according to the strategy for the node of length \( s \), we let the \( G \)-strategy act and then proceed to stage \( s + 1 \).

Verification. We define the true path of the construction recursively. The empty string \( \langle \rangle \) is on the true path. If \( \sigma \) is on the true path and \( \sigma \) is devoted to some \( R_{e,n} \)-requirement, then \( \sigma \) outcome is on the true path. If \( \sigma \) is on the true path and \( \sigma \) is devoted to some \( P \)-requirement, and \( \sigma \) is accessible at infinitely many stages, then \( \sigma \) is on the true path; otherwise, \( \sigma \) fin is on the true path. Note that an equivalent definition would be that the true path is formed by choosing from every level of the tree the leftmost node which is accessible at infinitely many stages.

We perform the verification as a sequence of claims.

Claim 5.5. \( \Gamma^A \) is total.

Proof. At every stage \( s \), we define \( \Gamma^A(x)[s] \) for all \( x < s \). Since \( A \) is r.e., and the use \( \gamma^A(x)[s] \) never increases, \( \Gamma^A(x) \) is defined for all \( x \).

Claim 5.6. If \( \sigma \) is an \( R_{e,n} \)-requirement, \( \sigma \) has outcome \( \inf \) at stage \( s \), \( \sigma \) is not initialised between stages \( s < t \), and \( y \leq 3k \) is such that \( \Psi^A_e(y)[s] \) was included in the maximum from which \( p \) was defined at stage \( s \), then \( y \in \text{dom} \left( \Psi^A_e \right) \) and \( \Psi^A_e(y)[t] = \Psi^A_e(y)[s] \).

Proof. The only way the conclusion might fail is if some \( P \)-strategy were to enumerate an element into \( A \) below \( \psi_e^A(y)[s] \) between stages \( s \) and \( t \). We consider the possibilities.

Since \( \sigma \) was not initialised, no \( P \)-strategy to the left of \( \sigma \) was accessible to do this. Similarly, no \( P \)-strategy \( \tau \) with \( \tau \text{fin} \subseteq \sigma \) could enumerate a new element into \( A \) without \( \ell_s(e') \) increasing, causing \( \tau \inf \) to be accessible and initialising \( \sigma \).

Any \( P \)-strategy to the right of \( \sigma \) or extending \( \sigma \) would have been initialised at stage \( s \) and so its next threshold would be no less than \( s \), which by our earlier assumption is greater than \( \psi_e^A(y)[s] \). So such a strategy cannot enumerate an element below \( \psi_e^A(y)[s] \).

Any \( P \)-strategy \( \tau \) with \( \tau \text{fin} \subseteq \sigma \) has \( (e', \ell_s(e')) > \psi_e^A(y)[s] \), and thus has already enumerated by stage \( s \) all the elements below \( \psi_e^A(y)[s] \) that it ever will.

Claim 5.7. Let \( \sigma \) be an \( R_{e,n} \)-requirement. Suppose \( \sigma \) was initialised at stage \( s_0 \), choosing an interval \([k, 3k]\), and \( \sigma \) was not initialised between stages \( s_0 < t \). Then there is an \( i < 2 \) and an \( x \in [k, 3k] \) such that \( f^A_{e,i}(x) \).
Proof. Since \([k, 3k]\) was chosen disjoint from every previously claimed interval, and the functions \(f^i_e\) are only defined within a claimed interval, if \(s\) is a stage with some \(f^i_e(x)\) defined with \(x \in [k, 3k]\), then \(s_0 \leq s\). By Claim 5.6 at every such stage \(s \leq t\), the domain of \(\Psi_e^A[s]\) grows by at least one element which is no more than \(3k\) and which is still in \(\text{dom } \Psi_e^A[t]\). Thus this can happen at most \(3k + 1\) many times. Since at most one \(f^i_e(x)\) definition is made by \(\sigma\) at each such stage \(s\), and there are \(4k + 2\) many pairs \((i, x)\) with \(i < 2\) and \(x \in [k, 3k]\), there is always a pair with \(f^i_e(x)\).

Claim 5.8. If \(\sigma\) is a strategy along the true path, \(\sigma\) is only initialised finitely many times.

Proof. By induction on \(|\sigma|\). The case when \(\sigma = \langle \rangle\) is trivial.

A strategy \(\sigma\) can only be initialised by the actions of strategies \(\tau \subseteq \sigma\).

If \(\tau\) is a \(P_e\)-requirement, and \(\tau\inf \subseteq \sigma\), \(\tau\) cannot initialise \(\sigma\).

If \(\tau\) is a \(P_e\)-requirement, and \(\tau\fin \subseteq \sigma\), then \(\tau\fin\) is on the true path. By definition of the true path, there is some stage after which \(\tau\) never again has outcome \(\text{fin}\). After this stage, \(\tau\) can never again initialise \(\sigma\).

If \(\tau\) is an \(R_{e,n}\)-requirement, let \(s_0\) be the last stage at which \(\tau\) is ever initialised. By Claim 5.6 at every stage \(s > s_0\) at which \(\tau\) initialises \(\sigma\), the domain of \(\Psi_e^A[s]\) grows by at least one element which is no more than \(3k\) and which never subsequently leaves. Thus this can happen at most \(3k + 1\) many times.

Claim 5.9. If \(\phi_e\) is total, \(\Gamma^A\) dominates \(\phi_e\).

Proof. Let \(\sigma\) be the \(P_e\)-strategy along the true path. Let \(s_0\) be the final stage at which \(\sigma\) is initialised, and let \(m\) be the threshold chosen at this stage. For an \(x\) with \(\langle e, x \rangle > m\), let \(s\) be the least stage such that \(\ell_s(e) > x\). By construction, \(\langle e, x \rangle\) will not enter \(A\) before stage \(s\).

At the first stage \(t \geq s\) when \(\sigma\) is accessible, \(\sigma\) will enumerate \(\langle e, x \rangle\) into \(A\) if no other \(P_e\)-strategy has already done so. When this happens, the \(G\)-strategy will redefine \(\Gamma^A(x) \geq \phi_e(x)\). By construction, all future redefinitions of \(\Gamma^A(x)\) will be at least \(\phi_e(x)\). Thus \(\Gamma^A(x) \geq \phi_e(x)\) for all \(x\) with \(\langle e, x \rangle > m\).

Claim 5.10. For every \(n \in \omega\), there is an \(i < 2\) and an \(x > n\) with \(x \in \text{dom} f^i\) such that for every \(y \leq x\) with \(y \in \text{dom} \Psi_e^A\), \(\Psi_e^A(y) < f^i_e(x)\).

Proof. Let \(\sigma\) be the \(R_{e,n}\)-strategy along the true path. Let \(s_0\) be the final stage at which \(\sigma\) is initialised, and let \([k, 3k]\) be the interval chosen at stage \(s_0\). Recall that we chose \(k > n\). Let \(i < 2\) and \(x \in [k, 3k]\) be the final pair for which \(\sigma\) defines \(f^i_e(x)\). We claim these are the desired values.

Suppose there were a \(y \leq x\) with \(y \in \text{dom} \Psi_e^A\) and \(\Psi_e^A(y) \geq f^i_e(x)\). Let \(s_1 > s_0\) be a stage such that \(y \in \text{dom} \Psi_e^A_{s_1}\) and \(A_{s_1} \upharpoonright \phi_e(y) = A \upharpoonright \phi_e(y)\). Let \(s_2 > s_1\) be a stage such that \(\langle e', \ell_s(e') \rangle > \phi^i_e(y)\) for every \(\tau\inf \subseteq \sigma\) a \(P_e\)-strategy. Let \(s_3 > s_2\) be a stage at which \(\sigma\) is accessible.

At stage \(s_3\), \(p \geq \Psi_e^A(y) \geq f^i_e(x) = q\). By construction, a new pair \(i' < 2\) and \(x' \in [k, 3k]\) will be chosen and \(f^{i'}_{e'}(x')\) defined, contradicting our choice of \(i\) and \(x\).

This completes the proof of Theorem 5.3.
6. The opposite of dominance

Hyperimmune-free degrees are in a certain way the counterpart of high degrees: Every high set \( A \) computes a function \( f \) which grows faster than every recursive function \([13, 14]\); every hyperimmune-free set \( A \) only computes functions \( f \) for which there is a recursive function growing faster than them (this recursive function depends on \( f \)). One can say that besides being low also having hyperimmune-free Turing degree is something like the opposite of being high. Then, every total \( A \)-recursive function is majorised by a recursive one. One could ask whether the same could be possible for the type of sets investigated in the present work.

**Definition 6.1.** Call a set \( A \) to be phif (hyperimmune-free with respect to partial functions) iff for every partial \( A \)-recursive function \( \psi \) there is a partial recursive function \( \phi \) and a constant \( k \) such that for every \( x \in \text{dom}(\psi) \) there is a \( y \in \text{dom}(\phi) \) with \( y \leq kx \) and \( \phi(y) > \psi(x) \).

**Theorem 6.2.** Every phif set \( A \) has hyperimmune-free Turing degree.

**Proof.** It is shown that a set \( A \) of hyperimmune Turing degree cannot be phif.

To show this, the following fact is used: There is an \( A \)-recursive function \( F \) such that for every infinite r.e. set \( W \) and every \( n \) there are infinitely many \( m \in W \) with \( F(m) = n \).

One can define such a function \( F \) inductively by starting a monotonically increasing function \( G \leq_T A \) not majorised by any recursive function and then letting \( F(m) = n \) for the least triple \( \langle e, n, k \rangle \) such that either \( \langle e, n, k \rangle = m \) or \( m \in W_{e,G(m)} \) and there are less than \( k \) numbers \( o < m \) with \( F(o) = n \land o \in W_{e,G(m)} \). It is clear that \( F \) is a total \( A \)-recursive function. Furthermore, a requirement given by a triple \( \langle e, n, k \rangle \) is satisfied when there are at least \( k \) numbers \( o \in W_e \) with \( F(o) = n \). One can see that whenever \( W_e \) is infinite then each requirement \( \langle e, n, k \rangle \) becomes eventually satisfied as there are infinitely many \( m \) with \( m \in W_{e,G(m)} \) where \( \langle e, n, k \rangle \) requires attention unless the requirement is satisfied; here the \( m \)-th requirement can only be denied attention when a higher order requirement, that is the 0-th, 1-st, \ldots or \( m-1 \)-th requirement is done and will be satisfied by defining \( F \) at one place accordingly. This happens of course only finitely often and then the \( m \)-th requirement will be satisfied eventually. So \( F \) has the requested properties.

Given \( F \), define a partial \( A \)-recursive function \( \psi \) as follows. On input \( x \) with \( 2^m \leq x < 2^{m+1} \) and \( F(m) = \langle i,j,k \rangle \), \( \psi(x) \) simulates the computations of \( \varphi_i(y) \) for inputs \( y \leq 2^{m+1} \cdot k \) until at least \( h = j \cdot 2^m + (x - 2^m) \) of these computations have converged with outputs \( z_0, z_1, \ldots, z_{h-1} \). Then \( \psi^A(x) \) takes the value \( 1 + z_0 + z_1 + \ldots + z_{h-1} \).

Now assume by way of contradiction that there is a partial recursive function \( \varphi_i \) and a \( k \) such that for almost all \( x \in \text{dom}(\psi) \) there is a \( y \leq kx \) in the domain of \( \varphi_i \) with \( \varphi_i(y) > \psi(x) \). Let \( j \) be the lim sup for \( m \to \infty \) of the numbers \( j_m \) where each \( j_m \) is the rounded-down value of \( 2^{-m} \cdot |\text{dom}(\varphi_i) \cap \{0, 1, \ldots, 2^{m+1} \cdot k\}| \). As \( j_m \in \{0, 1, 2, \ldots, 2k+1\} \) for each \( m \), the lim sup of the \( j_m \) must exist and is a number \( j \). The set \( E = \{m : j_m = j\} \) is r.e. and infinite. Hence there are infinitely many \( m \in E \) with \( F(m) = \langle i,j,k \rangle \). For each of these \( m \) there is an \( x \) such that \( 2^m \leq x < 2^{m+1} \) and \( j \cdot 2^m + (x - 2^m) = |\text{dom}(\varphi_i) \cap \{0, 1, \ldots, 2^{m+1} \cdot k\}| \). Now \( \psi(x) \) is defined and \( \psi(x) > \varphi_i(y) \) for every \( y \in \text{dom}(\varphi_i) \) with \( y \leq 2^{m+1} \cdot k \). This produces the desired contradiction and therefore \( i,k \) cannot destroy the witness \( \psi \) against \( A \) being phif. Hence, every phif set is hif, that is, has hyperimmune-free Turing degree.

The next result shows that phif sets are even recursive. Kummer's Cardinality Theorem \([8, 11]\) implies the following result, which confirmed a conjecture by Owings \([20]\).
Theorem 6.3. If a set $A$ of natural numbers, a natural number $k$ and a function $g$ with $k$ inputs satisfy
\[
\forall x_1, x_2, \ldots, x_k \ [x_1 < x_2 < \ldots < x_k \Rightarrow g(x_1, \ldots, x_k) \in \{0, 1, \ldots, k\}] - \{|A \cap \{x_1, \ldots, x_k\}|\}
\]
then $A \leq_T g$.

The next result uses this theorem now to prove that $A$ is recursive; the proof first shows that $A$ is $K$-recursive and then invokes the above result that $A$ has hyperimmune-free Turing degree in order to show that $A$ is recursive.

Theorem 6.4. If $A$ is phif, then $A$ must be recursive.

Proof. Suppose that $A$ is phif. Let $\psi^A(2^e + 2^{e+1}x) = \phi^A_e(x)$. Let $p$ and $\ell$ be such that for every $x \in \text{dom}(\psi)$, there is a $y \in \text{dom}(p)$ with $y \leq \ell x$ and $p(y) > \psi(x)$.

We will construct a partial $A$-recursive function $h = \phi^A_e$, and by the usual recursion theorem argument we may assume we already know $e$. Let $k = 2^{e+2}\ell$ and let $f$ be an $A$-recursive function with $f(m) = |A \cap \{x_1, \ldots, x_k\}|$ for the $m$-th tuple $(x_1, \ldots, x_k)$ with respect to a recursive enumeration of all $k$-tuples. For all sufficiently large $x \in \text{dom}(h)$, there is a $y \in \text{dom}(p)$ with $y \leq kx$ and $p(y) > h(x)$.

Construct a pair of sequences $\langle b_n \rangle_{n \in \omega}$ and $\langle c_n \rangle_{n \in \omega}$ as follows:

- $b_0 = 1$;
- $b_{n+1} = (k + 1)b_n + 1$;
- $c_0 = k$;
- $c_{n+1} = (k + 1)(b_{n+1} - b_n) - 1$.

The important properties of these sequences are the following:

$c_{n+1} < (b_{n+1} - b_n)(k + 1)$ and $c_{n+1} = kb_{n+1}$.

Let

$g(n) = |\{m : m \in \text{dom}(p) \land m < c_{n+1}\}| \% (k + 1)$.

That is, $g(n)$ is the residue when the number of elements in the domain of $p$ less than $c_{n+1}$ is reduced mod $(k + 1)$. Note that $g$ is $K$-recursive.

We construct $h$ as follows: for $(b_n + i) \in [b_n, b_{n+1})$, wait until $(k + 1)i + f(n)$ many elements less than $c_{n+1}$ have entered the domain of $p$. Then define $h(b_n + i)$ greater than the largest value of $p$ seen so far.

For any $n$ with $f(n) = g(n)$, let $i$ be such that

$$(k + 1)i + f(n) = |\{m : m \in \text{dom}(p) \land m < c_{n+1}\}|.$$

Note that $i \leq \frac{c_{n+1}}{k+1} < b_{n+1} - b_n$, so $b_n \leq b_n + i < b_{n+1}$. Then by construction, $h(b_n + i)$ is larger than $p(y)$ for all $y < c_{n+1}$. So $h(b_n + i)$ is larger than $p(y)$ for all $y < (b_n + i)k$. By our choice of $p$ and $k$, this can only happen finitely many times. So $f(n) = g(n)$ for at most finitely many $n$. By Theorem 6.3, $A \leq_T g$ and so $A \leq_T K$. As $A$ has also hyperimmune-free Turing degree, it follows that $A$ is recursive.
Theorem 7.1. An r.e. set is wttpdominant iff it is wtt-complete.

wttpdominant. Hence there is a wtt-incomplete wttpdominant set
wttpdominant. On the other hand, Example 1 actually shows that the half
which stands in contrast to the situation at Turing reducibility.

witnesses the corresponding lowness property.
