Abstract

Purpose of the study: In this study assessment of treatment results of old age children (13-18 years) with congenital recurrent clubfoot at the RISC’RTO’ by the method of transosseous osteosynthesis was done.

Materials and methods: In our clinic from 2004 to 2016 65 children (77 feet) aged 13-18 (mean age was 14.6 years) with congenital recurrent clubfoot have been treated. All patients were treated by Ilizarov method. In this group of patients together with insertion of wires in the tibia and foot, appropriate Ilizarov frame assembly we used surgical interventions on soft tissues, osteotomies and stabilizing surgeries.

Results: Long-term results (average 40 months follow-up) noted in 55 (84.6%) of patients by AOFAS (American Orthopedic Foot and Ankle Society) scale: In 67.3% of cases (37 patients) noted good treatment results, poor outcomes (26.3 ± 10.0 points according to AOFAS)-in 4 cases (7.3%).

Conclusion: Application of the method of transosseous osteosynthesis by Ilizarov in management of children with congenital recurrent clubfoot allows us to achieve desired results and to reduce possibility of recurrent development of the segment deformity.

Keywords: Clubfoot; Recurrence; Transosseous osteosynthesis; Older age children; Ilizarov; External fixator

Introduction

Congenital clubfoot is a malformation of the osseous, muscular and vascular systems associated with impaired activity central and peripheral nervous system as a result of total body dysplasia with mainly affecting the foot and tibia [1]. Annually over 100 thousand children are born in the world with this type of disease [2], which tends to recurrence within the growth process of a child [3,4]. In spite of quite sufficient study of this problem questions of etiopathogenesis didn’t find a single response. Patients of the age group ranged from 13 to 18, as a rule, have time to receive medical treatment (most of them many times) using various techniques: staged plaster bandage, different variants of tenoligamentocapsulotomies, stabilizing surgeries, instrumental correction [5-15]. However, according to several authors’ recurrence of the clubfoot ranged from 15-50%, which is associated not only with the disease itself but with a tendency to recur in the growth process of a child but with presence of rough postoperative scars delaying foot development. Therefore, surgical treatment of this group of patients is very difficult until now.

Techniques of transosseous osteosynthesis based on biological laws opened by academician Ilizarov are connected with dosed elimination of components of the foot deformity by means of gradual extension of shortened soft tissues, tendon-ligamentous apparatus of the foot and ability of the bone tissue to transformation [16,17]. Possibility to use various Ilizarov frame assemblies in sparing optimal rigidity of fixation of the foot bones with their dosed translation in necessary direction allows us to correct any foot deformity and/or its parts [4,11,13,14].
So, this study was done to evaluate results of surgical treatment of multicomponent recurrent foot deformity which can help orthopedic surgeons to solve this problem and to assist in reduction of recurrence rates.

**Materials and Methods**

In our clinic from October, 2004 to March, 2016 65 children (77 feet) aged 13-18 with congenital recurrent clubfoot (mean age was 14, 6 years) have been treated. Minimum follow-up after surgery was 10 months (average 40 months, ranged from 10 to 72 months). To assess the condition of the patients, the choice of the most appropriate method of treatment, the course of reparative processes and analysis of treatment results, we used the clinical and X-ray examination. Before treatment clinical evaluation of the ankle joint and the foot was done to examine people according to functional AOFAS scale [18]. Typical complaints to the deformity, pains in the foot while loading, limitation of motions in the ankle joint, violation of the support ability of the lower limb, fast fatigue and inability of long time walking, difficulty in choice of the shoes also and cosmetic defect of the segment because of its shortening and also presence of rough scars of the shin and foot skin. In observation of the patient’s tulips equinocavovarus adducts with prevailing of one or several components of the deformity were noted. In 44 children (67.8%) dominating of such a deformity components as equines and adduction were noted. It was associated with presence of scars from 8-20 cm on the posterior surface of the lower third of the tibia and medial plantar foot surface, soldered with subjacent tissues. In this group of patients were clinically noted joint contractures of operated foot. 9 patients (13.8%) had previous scars, but they were mobile. 12 patients (18.4%) have been treated before with conservative methods (plaster bandaging). In evaluation of patients function, pain syndrome and ability of hind-and middle foot to adaptation on the flat surface, total points according to AOFAS scale before our treatment varied until 36 points. We used X-ray examination to define degree of impaired anatomical correlations of bony structures of the tibia and the foot. On admitting to the stationary was done radiography of the foot with ankle joint in AP and ML views and also forefoot in AP view (plantar) with load.

We developed our scheme of surgical interventions in the older school age children considering clinical forms of the disease (Figure 1, classification of clubfoot by Diméglio [19]) and aged peculiarities of radiological anatomy of the foot bones [20]. We divided this group of patients into two subgroups depending on the existing level of foot shortening. All patients received wires in the tibia and the foot with corresponding assembly of the Ilizarov frame with hinge joints and an option of surgery on soft tissues and foot bones. In a pronounced norm and hypertrophic scars we used to do transverse incisions onto cicatricle tissues of the foot and or in cases of rough scars soldered with subjacent tissues-their maximum excision.

Treatment of children aged 13-18 with foot deformity with its shortening less than 2.0 cm. Foot deformity of the II degree by...
Dimeglio (5-10 points) noted in 18 patients (24 feet) was corrected intraoperative using Ilizarov frame by means of correcting triple (talo-navicular, calcaneo-cuboid, talo-calcaneal) arthrodesis of the foot (Figure 2a-2c) with preliminary intervention on soft tissues of the segment or dozed one using Ilizarov frame by means of osteotomy of the midfoot bones (cuneiform and cuboid bones) and calcaneus (Figure 3a-3c), if foot was rigid after surgical procedures on soft tissues (8 patients (10 feet)). Surgical intervention on soft tissues included percutaneous z-shaped achillotomy, tenotomy of flexors muscle of toes, capsulotomy of the metatarsophalangeal joints and plantotomy. In cases when osteotomy of the foot bones was done deformity correction by Ilizarov frame started on the 4-5 day.

Foot deformity of the III-IV degree by Dimeglio (10-20 points) noted in 17 patients (23 feet) was done dozed correction using Ilizarov frame starting from the 6-7 day after surgery with preliminary surgical intervention on soft tissues by percutaneous z-achillotomy, tenotomy of flexors muscle of toes, capsulotomy of the metatarsophalangeal joints and plantotomy. To prevent flexion contractures of the toes they were fixed with wires. Then, after gradual correction of foot deformity by Ilizarov frame triple arthrodesis was done as a stabilizing surgery (Figures 2 and 4). In case of pronounced muscular imbalance was done transfer of the tibia muscle tendons to the edge of the feet by the classic method.

Treatment of children aged 13-18 with combination of the foot deformity and its shortening. Shortening over 2.5 cm and more was an indication for lengthening. In shortening of the foot and presence of the deformity of the II degree (16 children (16 feet)) was done gradual correction and segment lengthening using Ilizarov frame by osteotomy of the midfoot (cuneiform and cuboid bones) and calcaneus (distraction osteogenesis by Ilizarov (Figures 3 and 5)). Correction started on the 4-5 day after surgery.

In cases of the III-IV degree of the foot deformity (14 patients (14 feet) with existing shortening of the segment after gradual deformity correction by Ilizarov frame was done triple arthrodesis of the metatarsophalangeal joints and plantotomy.
of the foot at first stage (Figure 2a-2c). Foot lengthening was
done in the second stage of treatment according to described
earlier our methods (distraction osteogenesis) (Figure 3a-3c).
In this group (patients with deformity and shortening of foot)
tendon transfer was done in 3 cases after lengthening of foot.

Foot lengthening was done by formation of distraction regenerate
in the midfoot area and calcaneus (Figure 3c).

The studies were approved by the institutional committee and
were performed in accordance with the ethical standards laid
down in the Declaration of Helsinki. All persons included into
the study gave their informed consent and the study of human
subjects followed the rules of clinical practice in the Russian
Federation (RF Ministry of Health order # 266).

Results

Results of comprehensive study allowed obtaining data which
dynamics served as an objective criterion of effectiveness of the
medical therapies. Gradual correction of foot deformity by Ilizarov
frame allowed us to overextend existed scars-changed soft
tissues and to correct all deformity components with moderate
hypercorrection 10-15 degrees because of the existing partial
elastic tissue retraction of the medial-planar foot surface after
frame removal. Duration of distraction and fixation depended
mainly on the degree of the deformity and foot shortening. Data
about duration of correction of foot deformity see in the Table 1.
Subsequent fixation of the segment by ilizarov frame in group of
patients without lengthening of foot was 45.4 ± 6.2 days.

In patients with deformity and shortening of foot average
amount of lengthening was 3.78 ± 0.9 cm, duration of fixation by
the frame-75.3 ± 7.4 days.

Postoperative complications were observed in 14 patients which
was 21.5% of the total number of treated patients of this group.

Among them inflammation of soft tissues around wires in 5
(7.7%), cutting of soft tissues with wires in 3(4.6%), premature
consolidation at the area of osteotomy in 2 (3.1%), subluxation of
the ankle joint in 2(3.1%) and cutting of wires out of the bone was
noted in 2 (3.1%) patients. All encountered complications have
been eliminated during treatment process and didn’t affect the
final result of it.

Long-term results (average 40 months, ranged from 10 to 72
months) of our treatment were analyzed in 55 patients (84.6%)
by point-based system AOFAS (Table 2). Among long-term
results there were distributed the following way: Good in 37
patient (67.3%), satisfactory in 14 (25.4%), poor -4 (7.3%).

In all cases after conducted treatment was noted improvement
of the functional condition of the foot and its cosmetic view
versus preoperative.

Discussion

Traditional methods of conservative treatment of recurrent
clubfoot in the group of old age children are ineffective [3-6].
In the front plan comes release of the hind- and medial-planar
areas of the foot or surgeries on the foot- and tibia bones with
external fixator [8-11]. However, extended surgeries on soft
tissues of the segment often lead to foot rigidity and formation
of rough painful postoperative scars [13,15,17]. So, according to
Lee et al. data more than a third of cases (35%) [21-24]. After
surgical treatment of the foot deformity required in the future
ostetomy of the foot bones. We consider that in correction
of congenital recurrent clubfoot in older children against scar-
soft tissue and anatomical abnormalities of the skeletal system
transossous osteosynthesis by ilizarov is a method of choice.

According to the data of Sadofieva [20] to the beginning of this age
period occurs ossification of the apophyses of tubular bones and
tarsal bones. Cartilaginous structure is saved in met epiphyseal growth plates of the tibia, short tubular bones of the foot and growth plates of apophyges. Based on these data we used selective approach for surgeries in patients of this group (osteofomy, arthrodesis, lengthening of foot). Gradual foot deformity correction by the Ilizarov frame allowed us to overextend existing scarring soft tissues and to correct all components of segment deformity with moderate hypercorrection 10-15 degrees to prevent recurrence development. In correction of the deformity using Ilizarov frame we corrected foot deformity by reduction of existing subluxations at the talonavicular and subtalar joints and (or) translation of bone fragments after performed osteotomies (Figures 3 and 6). In usage of the Ilizarov frame in Bradish et al. [22] study poor results were noted in 11.8% of cases. In Ferreira et al. study [3] in terms of observation on average in 58 months after treatment poor results after segment deformity correction by Ilizarov frame were noted in 13.2% of cases and recurrence of the deformity was found in 19 feet (50%). 12.1% of treated feet in Barbary study [5] had recurrence of some components of the clubfoot deformity after its correction using Ilizarov frame. In Ahmed paper unsatisfactory results were found in 27.8% cases [21]. But in this study have been observed partial recurrence of the treated foot deformity in 7.3% of cases. Cause of recurrent foot deformity in all cases was incompliance of patients with recommendations of orthopedic surgeon aimed at the preservation of obtained result.

It is important to note that all patients after correction of the rough segment deformity started walking with support on the plantar surface of the foot using special foot support made of rigid polyurethane foam trimmed with cloth for better adaptation of the foot to the support surface which was impossible in some techniques of the external frame correction [15].

Anyway, many colleagues told us about the good results of the usage of external fixator, where 72-84% of the cases were treated successfully [3,4,21,24,25]. In study of Grill and Franked [8] good treatment results were obtained in all cases. Any surgeons showed us that in some cases a period of work by external fixator was reached until 14 months [6,25].

But today there is no common assessment scale and surgical scheme for the treatment of clubfoot and its recurrences in older age children.

Some authors noted sufficient number of complication in the usage of the transosseous osteosynthesis method such as soft tissue inflammation, pronounced edema, cutting of soft tissues with wires, subluxations in the phalanx of toes, premature consolidation at the area of osteotomy etc. [3-5]. Some of them were noted in our study. Together with it we consider that main preventive measures of complications are observation of base principles of the technique of transosseous osteosynthesis by

Ilizarov and rational observation of patients in the postoperative period [8,11,13,15,22]. For instance, prevention of soft tissue inflammation around wires was compliance with the rules of aseptic and antiseptic, regular and well performed dressing procedures. In the first 3-4 postoperative days changing of bandages was done every day by the doctor, then every week. To prevent cutting of soft tissues it is necessary to insert wires with corresponding skin reserve between supports to which traction forces are directed during deformity correction process and also observe necessary rate and frequency of distraction forces at preservation of necessary stable fixation of bones in a frame. Observation of the rate and frequency of distraction of the treatment process, timely and regular X-ray once in 7-10 days during correction allowed avoiding premature consolidation at the area of osteotomy. Correct placement of the rods connecting support of the interior part of a segment with a distal ring on the tibia was done to prevent subluxation in correction of the foot equines. Passing of wires through the calcaneal body in different planes allowed avoiding their cut out of the bone during correction.

After removal of the Ilizarov frame patient’s limbs were immobilized with a plaster bandage from the upper part of the tibia up to foot toes in a position of hypercorrection of the foot up to 10-15° in all deformity components for the period 1.5-2 months. Patients are allowed to put the entire weight on the foot. After removal of the plaster bandage all the patients were recommended restorative treatment in the domiciliary clinic including wearing of an orthopedic shoe with an insole-pronator, limb immobilization with an Ankle-Foot Orthosis (AFO) for 6-12 months for the night, massage and redressing exercises for the foot and also physiotherapy aimed to improve trophic of the anterior-external group muscles of the tibia, foot and restoration of the range of motions in the ankle joint. Amplitude of motions in the ankle joint and joints of toes was restored up to initial one on the average in 4-6 weeks after the beginning of the active exercises. Lack of restorative treatment and refusal the rational shoe wearing and corrective insoles leads to developing of partial recurrence of the foot deformity which has been observed by us in 4 cases.

A limitation of our study is that we have not assessed the long-term effects of surgical treatment more than after 6 years. However, other authors have reported that favorable outcomes of such interventions persist until 107 month [3].

**Conclusion**

So, application of transosseous osteosynthesis method by Ilizarov in treatment of congenital recurrent clubfoot allows us to differentially perform surgical correction in children depending on the age peculiarities of the foot and degree of the deformity which is with combination of correct postoperative management and rational rehabilitation of patients contributes achieving of the good treatment result and minimizes possible deformity recurrence helping with social rehabilitation of a child.
