Pan-enteric dysmotility, impaired quality of life and alexithymia in a large group of patients meeting ROME II criteria for irritable bowel syndrome

Piero Portincasa, Antonio Moschetta, Giuseppe Baldassarre, Donato F. Altomare, Giuseppe Palasciano

INTRODUCTION

Irritable bowel syndrome (IBS) is a common, chronic biopsychosocial disorder of unknown etiology, affecting 10-20% of all individuals any one time. Psychological factors, altered motility and sensation disorders of the intestine can be variably associated with IBS. Such aspects have not been investigated simultaneously. The aim of this paper was to evaluate gastrointestinal motility and symptoms, psychological spectrum and quality of life in a large group of IBS patients in southern Italy.

METHODS: One hundred IBS patients (F:M=73:27, age 48±2 years, mean±SE) fulfilling ROME II criteria matched with 100 healthy subjects (F:M=70:30, 45±2 years). Dyspepsia, bowel habit, alexithymia, psycho-affective profile and quality of life were assessed using specific questionnaires. Basally and postprandially, changes in gallbladder volumes and antral areas after liquid meal and orocaeal transit time (OCTT) were measured respectively by ultrasonography and H2-breath test. Appetite, satiety, fullness, nausea, and epigastric pain/discomfort were monitored using visual-analogue scales.

RESULTS: Compared with controls, IBS patients had increased dyspepsia (score 12.6±0.7 vs 5.1±0.2, P<0.0001), weekly bowel movements (12.3±0.4 vs 5.5±0.2, P<0.0001, comparable stool shape), alexithymia (score 59.1±1.1 vs 40.5±1.0, P=0.001), poor quality of life and psycho-affective profile. IBS patients had normal gallbladder emptying, but delayed gastric emptying (T26: 35.5±1.0 vs 26.1±0.6 min, P=0.00001) and OCTT (163.0±5.4 vs 96.6±1.8 min, P=0.00001). Fullness, nausea, and epigastric pain/discomfort were greater in IBS than in controls.

CONCLUSION: ROME II IBS patients have a pan-enteric dysmotility with frequent dyspepsia, associated with psychological morbidity and greatly impaired quality of life. The presence of alexithymia, a stable trait, is a novel finding of potential interest to detect subgroups of IBS patients with different patterns recovered after therapy.

\textbullet{} CLINICAL RESEARCH \textbullet{}

Abstract

AIM: Psychological factors, altered motility and sensation disorders of the intestine can be variably associated with irritable bowel syndrome (IBS). Such aspects have not been investigated simultaneously. The aim of this paper was to evaluate gastrointestinal motility and symptoms, psychological spectrum and quality of life in a large group of IBS patients in southern Italy.

MATERIALS AND METHODS

Subjects

A total number of 200 adult subjects were studied prospectively and divided into 2 cohorts: 100 consecutive patients with IBS (27 males and 73 females) and 100 healthy subjects (30 males and 70 females) with their age and body size matched. The two groups were also comparable for years of education (9.3±1.5 years and 9.6±1.3 years in healthy and IBS, respectively). The characteristics of patients are depicted in Table 1. There was no difference in sex ratio, age and body size. The percentage of non-coffee drinkers and smokers was greater in IBS than in healthy subjects (0.02<P<0.03). The IBS group was composed of out-patients, with a firm diagnosis through positive identification of the ROME II diagnostic criteria[41]. With the inclusion criteria used in this study, the specificity of IBS diagnosis was about 98%[41,45]. Mean years since first diagnosis have been 5.9 years with bowel habit alternating between diarrhea and constipation, according to standardized criteria[41]. During the above mentioned period, patients had tried several - albeit poorly effective - therapeutic trials with the help of their family practices. All patients were symptomatic at the time of the study, and lower abdominal discomfort or pain was the main reason for seeking medical advice, and none was on specific therapy for IBS at the time of evaluation. There was no coexistent disease and all patients had normal haematology, biochemistry, urinalysis, together with a normal colonoscopy.

http://www.wjgnet.com/1007-9327/9/2293.asp
or barium enema if aged over 50 years. Excluded were subjects if they had a history of gastrointestinal surgery. Female subjects were excluded if they were pregnant, breast feeding, or hysterectomised and were studied during the first phase of the menstrual cycle or while taking oestrogen/progesterone contraceptive medication. Drugs and cigarette smoking were not allowed for 48 hours prior to the study while alcohol and caffeine containing drinks were stopped 24 hours prior to the study. All subjects smoked less than 5 cigarettes per day and drank below the recommended safe alcohol limit (that is less than 21 units/week).

Because lactose maldigestion-intolerance and IBS may have almost identical symptoms,[16] all patients were screened by lactose H₂-breathe test, which was invariably negative. Healthy volunteers were recruited from staff members and with the help of local family practices. Laboratory investigations were normal (as above) in all healthy subjects and there was a negative toxicology for substances of abuse. All subjects gave informed consent to join the study which was approved by the Ethics Committee of Bari University Hospital.

Measures
Symptomatology was assessed by focusing on an estimate of the maximum degree of lower abdominal pain or discomfort, and abdominal bloating in the previous 12 months was assessed by visual analogue scales (VAS).[17] The weekly frequency of bowel movements over a time span of one month was estimated by a self-assessed diary. A specific stool form scale was also used based on a semi-quantitative score.[18] To carefully characterise the association between IBS and functional dyspepsia,[19] the presence and severity of dyspeptic symptoms were quantified in two ways: validated semiquantitative score[20]; and self-assessed VAS of upper gastrointestinal perception monitoring appetite, satiety, nausea, abdominal fullness and upper abdominal (epigastric) pain or discomfort.[21] In the latter case, scores were obtained at baseline (i.e. time 0) and at 15, 30, 45, 60, 90 and 120 min postprandially. The Middlesex Hospital Questionnaire (MHQ) symptom check list was used to investigate six symptoms: anxiety, phobic behavior, obsessive-compulsive behavior, somatization, depression, and hysteria.[22] Traits of alexithymia were assessed by the Toronto Alexithymia scale based on a 20-item scale (TAS-20)[23] with the validated Italian translation.[24,25] A final score ≥61 was considered positive for alexithymia, while a score ranging from 50 to 60 was “border line”[25]. The short form check list (SF-36) was used to assess HRQOL in the following 8 domains: general health, physical functioning, role-physical, role-emotion, social functioning, mental health, body pain, and vitality.[26,27].

Motility studies
After an overnight fast, subjects attended the Functional Investigations Unit. Standard criteria recently reviewed by our group[28] were used to study gallbladder and gastric emptying by functional ultrasonography in response to a liquid test meal, consisting of 200 mL solution totalling 13 g (39 %) fat, 10 g (13 %) protein and 35 g (48 %) carbohydrates, calorie content 1 270 kJ, 365 mmol /L (Nutridrink®, Nutricia, Milano, Italy), which was consumed within 2 min. Gallbladder emptying was assessed by monitoring fasting and postmeal course of gallbladder volumes. Sagittal and transverse scans of the gallbladder at its largest dimension were obtained at 5-15 minute intervals over 2 hours. Gastric emptying was assessed by monitoring fasting and postmeal course of antral areas.[17,29] Oro-caecal transit time was measured simultaneously with ultrasonographic studies by hydrogen breath test using 10 g lactulose and collecting the breath with a portable equipment (EC60-Gastrolyzer, Bedfont, USA).[30]

Statistical analysis
All calculations were performed with the NCSS 2001 statistical software (Kaysville, UT, USA, see http://www.ncss.com/). Results were given as mean ± standard error (SE). Differences in emptying curves were evaluated by two way ANOVA repeated-measures followed by Fisher’s LSD multiple comparison test. Differences of means between healthy and IBS were evaluated using the Student’s t test for unpaired data. Linear regression analysis was performed by the method of least square. The chi-square test was used to assess associations between categorical data. A two-tailed probability (P) value of less than 0.05 was considered statistically significant[31,32].

RESULTS
All subjects tolerated the tests well. Table 1 also shows that VAS scores for lower abdominal pain and bloating were significantly higher in IBS patients than in healthy subjects. Whereas the frequency of bowel movements was greater in IBS patients than in healthy subjects (12.3±0.4 vs 5.5±0.2 evacuations/wk, P=0.00001) (Figure 1A), stool form was similar (Buckley score: 3.9±0.1 vs 3.5±0.1 in patients and controls, respectively).(Figure 1B).

Figure 1 A: Significantly more bowel movements in IBS patients than in healthy subjects. B: Comparable score for stool form between IBS patients and healthy subjects. Results are expressed as individual data and median (horizontal line).

Figure 2 Significant dyspepsia in IBS patients compared with healthy subjects. Results are expressed as individual data and median.
Mean score of dyspepsia was greater in patients than in healthy subjects (12.6±0.7 vs 5.1±0.2, P<0.0001), an abnormal score was found in 75 % and 5 % of patients and healthy subjects, respectively (P<0.0001, Figure 2). As expected, the perception of satiety and appetite (both at fasting and as postprandial) was positively correlated with HRQOL (-0.34<r<-0.37, P<0.0001). There was no difference in appetite and satiety between IBS patients and healthy subjects (either at baseline and postprandially). By contrast, the AUC during 120 min was invariably greater in IBS than in control subjects for nausea (58.0±14.1 vs 39.9±11.0, P=0.002), fullness (133.5±26.1 vs 171±11.9, P=0.00002) and pain/discomfort (75.1±24.2 vs 2.5±0.6, P=0.002). Time-dependent profiles for these scores are depicted in Figure 3.

### Table 1 Patient characteristics in study group (mean ±SE)

|                | IBS         | Healthy     | P*    |
|----------------|-------------|-------------|-------|
| No of subjects | 100         | 100         |       |
| Female: Male ratio | 73:27     | 70:30       | NS    |
| Age (yr)       | 48±2        | 45±2        |       |
| BMI (Kg/m²)    | 23.5±0.4    | 22.9±0.3    | NS    |
| Coffee-drinkers No (%) | 30 (30%)   | 45 (45%)    |       |
| Smokers No (%) | 30 (30%)    | 15 (15%)    |       |
| Lower abdominal pain (VAS, cm) | 5.9±0.1 | 0.04±0.01 | 0.00001 |
| Abdominal bloating (VAS, cm) | 6.2±0.1 | 0.1±0.02 | 0.00001 |

*pStudent’s t test or χ² for comparison of proportions, VAS=visual analogue scale.

Results from the MHQ questionnaire are given in Figure 4A which shows that IBS patients had significantly higher scores for anxiety, somatization, phobia and depression than healthy subjects. Results from the TAS 20 questionnaire on alexithymia are given in Figure 4B which shows a significantly increased score in IBS patients (59.1±1.1) compared to healthy subjects (40.5±1.0). An abnormal (i.e. >61) score for alexithymia was found in 43 % of patients and in 2 % of healthy subjects. Mean scores of SF-36 are reported in Figure 5 which shows that HRQOL was significantly poorer for all domains in IBS patients compared with healthy subjects. There was no difference between IBS patients and healthy subjects with respect to gallbladder motility, i.e. fasting and postprandial volumes and half-emptying times (Table 2). Concerning gastric motility, the mean cross-sectional antral areas at fasting and immediately after the test meal were comparable between IBS patients and healthy subjects. However, postprandial minimal antral areas were significantly larger and half-emptying time longer in IBS than in healthy subjects (Table 2, Figure 6). With respect to OCTT, basal levels of H₂ were invariably ≤10 p.p.m. in all subjects (i.e. absence of bacterial overgrowth) and did not differ between IBS patients and healthy subjects. OCTT, however, was increased by 62 % in IBS patients compared with healthy subjects (Table 2) with scattered distribution depicted in Figure 7. A value of OCTT above 130 min, representing the upper limit of normal (mean+2SDs), was found in 70 % of patients and in 2 % of healthy subjects (P=0.000001).

Overall, the score of dyspepsia was positively correlated with OCTT (r=0.38, P=0.0001) but not with gastric emptying speed. Also, the dyspepsia score was negatively correlated with all domains of HRQOL (-0.34<r<-0.43, P<0.001), while there was a positive correlation with somatization (r=0.32, P=0.001), anxiety (r=0.29, P=0.002) and alexithymia (r=0.47, P=0.00001). Frequency of bowel movements increased with anxiety (r=0.39,
P=0.00001), somatization (r=0.34, P=0.0004) and alexithymia (r=0.52, P=0.000001).

Figure 4 A: Scores of psychological disorders (mean ± SE, *0.0009<P<0.04). B: Scores of alexithymia (individual data and median) in IBS patients and healthy subjects.

Figure 5 Profiles of health-related quality of life-HRQOL (SF-36 questionnaire) for IBS patients and healthy subjects. Data are mean±SE. Significantly poorer HRQOL for all 8 scales in IBS patients compared with healthy subjects. Legend: Ph, physical; soc, social.

Figure 6 Time-course of gastric emptying in IBS patients and healthy subjects after ingestion of 200 mL of standard liquid meal. Symbols indicate mean (SE is very small and not visible at each time-point). IBS patients had impaired emptying with larger postprandial antral areas (expressed as % of basal area) than healthy subjects. See also Table 2 for half-emptying time differences.

Table 2 Motility indices in study group (mean ± SE)

|                | IBS      | Healthy | P*                |
|----------------|----------|---------|-------------------|
| No of subjects | 100      | 100     |                   |
| Gallbladder (volume) | 21.4±1.0 | 22.0±0.9 | NS               |
| Fasting (mL)   | 3.1±0.1  | 3.4±0.1 | NS                |
| Postprandial residual, mL (%) | 5.3±0.6 | 5.7±0.3 | NS                |
| T50 (min.)    | 20.1±0.9 | 21.4±0.6 | NS               |
| Stomach (antral area) | 10.4±0.2 | 11.8±0.2 | 0.001             |
| Fasting (cm²)  | 23.4±1.2 | 25.7±0.9 |                   |
| Postprandial maximal (cm²) | 6.1±1.0  | 2.8±0.5  | 0.02              |
| Postprandial minimal (%) | 6.1±1.0  | 2.8±0.5  | 0.02              |
| T50 (min.)    | 35.5±1.0 | 26.1±0.6 | 0.00001           |
| Small bowel   | 161.9±5.5 | 96.6±1.8 | 0.00001           |
| Oracoeal transit time (min.) | 360      | 300     |                   |

*Student’s t test, OCTT=oracoeal transit time, NS=not significant. Indices of gallbladder motility: fasting volume (mean of 3 measurements at -15, -5 and 0 min before test meal, expressed in mL), residual volume (minimum volume measured postprandially, in mL) and half-emptying time (T50, time to achieve 50% decrease of fasting volume). Indices of stomach emptying: fasting antral area (mean of 3 measurements at –15, -5 and 0 min before test meal, expressed in cm²), maximal antral area at 2 min postmeal in cm², minimal postprandial antral area during the 2-hour observation period (expressed in %, normalized to maximal area after subtracting basal areas: i.e. 100x(A - a)/(A - a)), where A = postprandial area at any given time; a = basal area; A = area at 2 min postprandially and half-emptying time (T50).

DISCUSSION

We used an integrated approach in a large group of IBS patients to investigate gastrointestinal motility patterns in relation to symptoms, quality of life and psychological comorbidity. We believe that the present study may offer a fairly representative picture of IBS characteristics in southern Italy. The ROME II criteria[4] were chosen because they perform well in the clinic and they have greater simplicity than other less recent criteria[1]. Due to the setting where the study was performed (i.e. a tertiary referral center), caution must be expressed in interpreting our results, for at least two reasons. Firstly, only a minority of IBS patients were thought to consult physicians[3] and secondly,
characteristics of patients seen in a third referral center might differ from those of patients referred to primary or secondary care\cite{25,34}. Nevertheless, IBS patients had multiple and simultaneous gastrointestinal motility defects involving stomach and intestine at a different extent, and were associated with diffuse gastrointestinal symptoms, abnormal psychological status, including alexithymia, and poor quality of life.

Ultrascanography was chosen as a non-invasive and validated technique to assess both gallbladder\cite{35,36} and gastric emptying\cite{17,19,37-40} simultaneously\cite{28}. The protocol we employed, moreover, was further informative due to the simultaneous assessment of small bowel transit by H2-breath test. Such a novel combined procedure allows a one-day (and time-saving) test for studying upper gastrointestinal motility in a clinical setting.

Despite “normal” feeling of appetite and satiety, IBS patients had strikingly abnormal upper gastrointestinal perception for nausea, fullness, epigastric pain/discomfort, both at fasting and postprandially. This was also the case in gastrectomized patients\cite{42}. Thus, ingestion of 200 mL of a moderately caloric, isomotic test meal might prove useful in identifying groups of patients with dyspepsia, as also proposed in different clinical settings\cite{43}. About 30% of IBS patients included in this study had delayed gastric emptying, as was found in other gastrointestinal functional disorders such as dyspepsia and slow transit constipation\cite{44}. Although this study was primarily focusing on patients with lower abdominal symptoms for IBS, we found that the score for dyspepsia was abnormal in about two-thirds of patients, as was also reported by age\textit{us} et al. in the Swedish population\cite{44}. Taken together, these findings suggest that dyspepsia and IBS are closely related and develop as a continuum\cite{45}. No close correlation existed between delayed gastric emptying and dyspepsia. Indeed, gastric emptying was defective only in a subgroup of dyspeptic patients and this also seemed to be the case in IBS patients. Moreover, both symptoms or gastric half emptying times were poor predictors of gastrointestinal dysmotility in functional dyspepsia\cite{44}. Also, dyspeptic symptoms might originate from an altered fundic receptive relaxation (not measured in the present study) and/or from disorders of other organs, including duodenum under acidic stress\cite{45}.

At variance with an early study in a scant number of IBS patients\cite{46}, we found no gross evidence for impaired gallbladder motility. Differences in selection criteria might partly explain the variability. CCK played a key role in postprandial gallbladder contraction, and abnormal sensitivity of the gallbladder smooth muscle to exogenous CCK has been reported in IBS\cite{47}. Apparently, the defect was absent postprandially, since either a high-fat\cite{47} or a low-fat (this study) liquid meal yielded similar gallbladder contractions. Whether or not the trend we showed of faster refilling in IBS points to the Swedish population\cite{44}. Taken together, these findings suggest that dyspepsia and IBS are closely related and develop as a continuum\cite{45}. No close correlation existed between delayed gastric emptying and dyspepsia. Indeed, gastric emptying was defective only in a subgroup of dyspeptic patients and this also seemed to be the case in IBS patients. Moreover, both symptoms or gastric half emptying times were poor predictors of gastrointestinal dysmotility in functional dyspepsia\cite{44}. Also, dyspeptic symptoms might originate from an altered fundic receptive relaxation (not measured in the present study) and/or from disorders of other organs, including duodenum under acidic stress\cite{45}.

At variance with an early study in a scant number of IBS patients\cite{46}, we found no gross evidence for impaired gallbladder motility. Differences in selection criteria might partly explain the variability. CCK played a key role in postprandial gallbladder contraction, and abnormal sensitivity of the gallbladder smooth muscle to exogenous CCK has been reported in IBS\cite{47}. Apparently, the defect was absent postprandially, since either a high-fat\cite{47} or a low-fat (this study) liquid meal yielded similar gallbladder contractions. Whether or not the trend we showed of faster refilling in IBS points to the Swedish population\cite{44}. Taken together, these findings suggest that dyspepsia and IBS are closely related and develop as a continuum\cite{45}. No close correlation existed between delayed gastric emptying and dyspepsia. Indeed, gastric emptying was defective only in a subgroup of dyspeptic patients and this also seemed to be the case in IBS patients. Moreover, both symptoms or gastric half emptying times were poor predictors of gastrointestinal dysmotility in functional dyspepsia\cite{44}. Also, dyspeptic symptoms might originate from an altered fundic receptive relaxation (not measured in the present study) and/or from disorders of other organs, including duodenum under acidic stress\cite{45}.

At variance with an early study in a scant number of IBS patients\cite{46}, we found no gross evidence for impaired gallbladder motility. Differences in selection criteria might partly explain the variability. CCK played a key role in postprandial gallbladder contraction, and abnormal sensitivity of the gallbladder smooth muscle to exogenous CCK has been reported in IBS\cite{47}. Apparently, the defect was absent postprandially, since either a high-fat\cite{47} or a low-fat (this study) liquid meal yielded similar gallbladder contractions. Whether or not the trend we showed of faster refilling in IBS points to
similar to that derived from subjects across different cultures in the USA and UK. This finding underscored the internal consistency of HRQOL questionnaires. Taken together, our findings confirmed that although IBS was not a life-threatening condition, it could lead to significant impairment of quality of life, at least in the subgroup of patients seen in a tertiary referral center.

In conclusion, these data show that IBS patients have a pan-entric dysmotility with frequent dyspepsia, associated with psychological morbidity and greatly impaired quality of life. The presence of alexithymia, a stable trait, is a novel finding of potential interest to detect subgroups of IBS patients with different patterns of recovery after therapy.
