Abstract. The investigation of the mechanism responsible for electroweak symmetry breaking is one of the most important tasks of the scientific program of the Large Hadron Collider. The experimental results on the search of the Standard Model Higgs boson with 1 to 2 fb\(^{-1}\) of proton proton collision data at \(\sqrt{s} = 7\) TeV recorded by the ATLAS detector are presented and discussed. No significant excess of events is found with respect to the expectations from Standard Model processes, and the production of a Higgs boson is excluded at 95% Confidence Level for the mass regions 144-232, 256-282 and 296-466 GeV.

1. Introduction

The search for the Standard Model (SM) Higgs boson, is one of the most important priorities of the Large Hadron Collider (LHC) scientific program. A recent review of the theory of the SM Higgs is available here [1]. Direct searches at the CERN LEP collider exclude the existence of this boson with a mass \(m_H\) lower than 114.4 GeV [2]. Searches by the CDF and D0 experiments at the Fermilab \(p\bar{p}\) collider have explored the Higgs boson mass up to 200 GeV. The most recent results on this search at the Tevatron collider have been presented in this conference [3].

Early results on SM Higgs boson searches recently performed by the ATLAS and CMS experiments at the LHC, using a data samples of proton-proton collisions at \(\sqrt{s} = 7\) TeV corresponding to an integrated luminosity from 1 to 2 fb\(^{-1}\), are also available.

In this paper the results on this search from the ATLAS detector [4] are presented. The results on the study performed by CMS are available here [5]. The channels analysed by ATLAS to search for this boson are summarized in Table 1.

The following sections describe in some detail the results achieved in each of these channels. A particular attention is dedicated to the decay channels \(H \rightarrow \gamma\gamma\), \(H \rightarrow WW(\ast) \rightarrow l\ell\nu\nu\) and \(H \rightarrow ZZ(\ast) \rightarrow 4l, l\ell\nu\nu\) as they play an important role in setting the overall result of this study. The analyses take into account the main systematic experimental effects, such as those related to the calibration and reconstruction efficiencies of electrons, muons, tau decays to hadronic final states, jets, transverse missing energy and b-tagging. Theory uncertainties associated to background processes as well as to the Higgs boson signal are also taken into account. The relative uncertainty on the measurement of integrated luminosity, \(\Delta L/L = 3.7\%\), is also included. The theory uncertainties on the production cross section and decay branching fractions of the Higgs boson are taken from [15].

No significant excess of events is found with respect to the expectations from Standard Model processes, and hence exclusion limits on the production cross section are set at 95% Confidence Level (C.L.) with a statistical analysis based on the \(CL_s\) [16] method.

1. Introduction

The search for the Standard Model (SM) Higgs boson, is one of the most important priorities of the Large Hadron Collider (LHC) scientific program. A recent review of the theory of the SM Higgs is available here [1]. Direct searches at the CERN LEP collider exclude the existence of this boson with a mass \(m_H\) lower than 114.4 GeV [2]. Searches by the CDF and D0 experiments at the Fermilab \(p\bar{p}\) collider have explored the Higgs boson mass up to 200 GeV. The most recent results on this search at the Tevatron collider have been presented in this conference [3].

Early results on SM Higgs boson searches recently performed by the ATLAS and CMS experiments at the LHC, using a data samples of proton-proton collisions at \(\sqrt{s} = 7\) TeV corresponding to an integrated luminosity from 1 to 2 fb\(^{-1}\), are also available.

In this paper the results on this search from the ATLAS detector [4] are presented. The results on the study performed by CMS are available here [5]. The channels analysed by ATLAS to search for this boson are summarized in Table 1.

The following sections describe in some detail the results achieved in each of these channels. A particular attention is dedicated to the decay channels \(H \rightarrow \gamma\gamma\), \(H \rightarrow WW(\ast) \rightarrow l\ell\nu\nu\) and \(H \rightarrow ZZ(\ast) \rightarrow 4l, l\ell\nu\nu\) as they play an important role in setting the overall result of this study. The analyses take into account the main systematic experimental effects, such as those related to the calibration and reconstruction efficiencies of electrons, muons, tau decays to hadronic final states, jets, transverse missing energy and b-tagging. Theory uncertainties associated to background processes as well as to the Higgs boson signal are also taken into account. The relative uncertainty on the measurement of integrated luminosity, \(\Delta L/L = 3.7\%\), is also included. The theory uncertainties on the production cross section and decay branching fractions of the Higgs boson are taken from [15].

No significant excess of events is found with respect to the expectations from Standard Model processes, and hence exclusion limits on the production cross section are set at 95% Confidence Level (C.L.) with a statistical analysis based on the \(CL_s\) [16] method.

| decay channel | integrated luminosity, fb^{-1} | mass range search, GeV |
|---------------|-------------------------------|------------------------|
| $H \rightarrow \gamma\gamma$ [6] | 1.08 | 110-150 |
| $W, ZH \rightarrow l\nu, l\bar{b}$ [7] | 1.04 | 110-130 |
| $H \rightarrow \tau^+\tau^-$ [8, 9] | 1.06 | 110-150 |
| $H \rightarrow WW^{(*)} \rightarrow l\nu l\nu$ [10] | 1.70 | 110-300 |
| $H \rightarrow ZZ^{(*)} \rightarrow llll$ [11] | 2.1 | 110-600 |
| $H \rightarrow ZZ \rightarrow l\nu l\nu$ [12] | 1.04 | 200-600 |
| $H \rightarrow ZZ \rightarrow l\bar{q}q$ [13] | 1.04 | 200-600 |

Table 1. The Higgs boson decay channels studied by ATLAS and reported in this paper (The results on the study of the decay channel $H \rightarrow WW^{(*)} \rightarrow l\nu l\nu$, available in [14], are not included in this paper, nor in the overall statistical combination described on the last section). The integrated luminosity related to each of the processes analysed is also given.

using the profile likelihood ratio [17] as test statistic. Finally, the statistical combination of the findings from each channel is presented in discussed in the last section.

2. $H \rightarrow \gamma\gamma$

The $H \rightarrow \gamma\gamma$ decay represents one of the few Higgs processes, whose final state can be fully reconstructed experimentally. Despite the low branching ratio, BR($H \rightarrow \gamma\gamma$) ≈ 2 × 10^{-3} for a Higgs boson with mass $m_H = 120$, this channel provides good experimental sensitivity in the mass region below 150 GeV [6]. The production cross section of this process is about 0.04 pb.

The background to this final state can be subdivided in two classes: irreducible and reducible. The irreducible background is made by direct production of diphoton events from the scattering of the initial proton constituents, that can be described by Born, bremsstrahlung and box Feymann diagrams. The inclusive cross section is about 30 pb. The theoretical prediction is calculated at the next-to-leading order (NLO) and it is known with an uncertainty of about 20%. The reducible background is made by $\gamma$-jet and jet-jet QCD processes, where one or two jets are misidentified as photons, respectively.

The excellent performance of the ATLAS electromagnetic calorimeter is able to ensure a good jet-photon separation, thanks in particular to the fine granularity along the pseudorapidity $\eta$. This allows to strongly reduce the level of contaminations due to the misidentified photon background arising from jet production. In the offline reconstruction photons are classified as “unconverted” (electromagnetic calorimeter clusters with no matching with tracks in the Inner Detector) and “converted” (clusters that match with a track pair, or a single track, consistent with the hypothesis with a photon conversion in the material of the Inner Detector). The single photon reconstruction efficiency is ≈ 98%, while the identification efficiency ranges typically from 75% to 90% for photon transverse energies between 25 and 100 GeV. The purity of the sample (fraction of genuine diphoton events) is about 72%. After selection, the fraction of candidates with at least one converted photon is 64%.

Events with two isolated high-quality photons are selected in the pseudorapidity range $\eta < 1.37$ and $1.52 < |\eta| < 2.37$, with $p_T > 40$ GeV for the leading photon, and $p_T > 25$ GeV the subleading photon. An accurate mass reconstruction is mandatory to maximize the signal-to-background ratio, and hence have a good sensitivity to $\gamma\gamma$ resonances. The
Alejandro Nisati, ATLAS Coll.

The reconstructed width of the Higgs boson peak is expected to be fully dominated by the experimental resolution. The experimental resolution is composed by the single-photon energy measurement accuracy, as well as by the diphoton opening angle in space. For most of the $H \rightarrow \gamma\gamma$ topologies, the angular resolution plays an important role, and therefore it is important to get an accurate measurement of the photon direction of flight. The ATLAS electromagnetic calorimeter allows to also measure the photon flight direction with an angular resolution, in case of unconverted photons, of about 14 mrad at $\eta=0$, a factor $\approx 4$ smaller than the accuracy that is obtained using the average pp interaction point and its spread. An even better resolution is achieved if at least one of the two photons is converted. This allows to obtain a $\gamma\gamma$ invariant mass resolution $\delta(m_{\gamma\gamma}) \sim 1.7$ GeV at $m_{\gamma\gamma}=120$ GeV, dominated by the photon energy resolution. The analysis is then performed classifying the selected events in five complementary categories, depending on whether none, one or both photons are converted, and on their measured pseudorapidity. For each category, the $m_{\gamma\gamma}$ invariant mass distribution is fitted with an exponential falling distribution to describe the background continuum, superimposed to a “crystal-ball” function representing the Higgs boson signal.

The number of selected events in the 100 - 160 GeV mass range is found to be 4846, whose measured number of diphoton events is $3650 \pm 100 \pm 290$. The first uncertainty is statistical, the second is systematic, arising from the estimation made with the control region. Figure 1(a) shows the reconstructed invariant mass spectrum.

![Figure 1(a)](image1.png)

**Figure 1.** (a) Distribution of the reconstructed invariant mass. The exponential fit to the full data sample of the background only hypothesis, as well as the expected signal for a Higgs boson of 120 GeV, mass with five times the production cross section, are also shown. (b) 95% confidence level upper limit on a Standard Model-like Higgs boson production cross section, relative to the Standard Model cross section, as a function of the Higgs mass hypothesis. The solid line describes the observed limit, while the dashed line shows the median expected limit assuming no Higgs boson. The bands indicate the expected fluctuation around this limit as 1 and 2 σ level.

The total relative systematic uncertainty on the expected signal yield is 12%, dominated by the photon reconstruction and identification efficiency. The uncertainty on the background measurement is between 5 events at $m_H = 110$ GeV and 3 events at $m_H = 150$ GeV, in a mass interval 4 GeV wide. No evidence of a significant excess of events on top of the background level is found. Exclusion limits on the inclusive production cross section of a Standard Model-like Higgs boson relative to the Standard Model cross section are derived. The result, including systematic uncertainties, are shown in Figure 1(b). The observed limit on the cross section production ranges between 2.0 and 5.8 times those
predicted by the SM. The expected median limit in the case of no signal, varies from 3.3 to 5.8 times the SM predictions. The expected and the observed limits vary within less than two sigma in the full mass interval analysed.

3. \( W/Z + H, \ H \rightarrow b\bar{b}, \text{ and } H \rightarrow \tau^+\tau^- \)

The decay \( H \rightarrow b\bar{b} \) is of particular importance as it is one of the few channels that offers the possibility of measuring directly the Higgs couplings to quarks. It also plays an important role in the search of this boson in the mass region below 140 GeV. It is the dominant Higgs decay at low mass, but the QCD jet background makes this search in the inclusive channel impossible. On the contrary, it is promising in the associated production with gauge bosons \( W, Z \). ATLAS has performed an analysis, based on an integrated luminosity of \( L=1.04 \text{ fb}^{-1} \), searching for \( H \rightarrow b\bar{b} \) produced in association with a \( W \) or a \( Z \). The leptonic decay of the boson is used both for trigger and offline event preselection. The analysis proceeds requiring exactly two b-tagged jets [18] with \( p_T > 25 \text{ GeV} \). The \( t\bar{t} \) production and single \( t \) are the dominant backgrounds in the \( WH \) channel; other important backgrounds are \( W+jets \) and QCD multijet production. The \( Z+jets \) production is the dominant background in the \( ZH \) channel; other important backgrounds are \( t\bar{t} \) and diboson production. The study focuses on the analysis of the jet-jet invariant mass \( m_{b\bar{b}} \), where the Higgs signal should appear as a bump on top of the background continuum. Figure 2(a) shows the distribution of \( m_{b\bar{b}} \) after all selection cuts, for the \( ZH \) associated production.

In this study the background contributions are either measured directly from data, or evaluated from Monte Carlo (MC) simulations, and validated with data control samples. The total relative uncertainty on the overall background is about 9\% for both associated production modes. The systematic uncertainty on the Higgs boson yield is dominated by the uncertainty on the b-tagging efficiency, about 17\%; the uncertainty on the Jet Energy Scale (JES) produces a relative uncertainty of about 8\% on the signal yield.

No event excess is found, and 95\% C.L. exclusion limits are set as a function of the Higgs boson mass. In the mass range 110-130 GeV, a production cross section of about 10-15 times the one predicted the SM is excluded. The observed limits are within about 1\(\sigma\) the expected limits. More details of this analysis are available here [11].

The inclusive \( H \rightarrow \tau^+\tau^- \) decay is promising for searches in the mass range 110< \( m_H <140 \text{ GeV} \). The Vector Boson Fusion process (VBF [1]) offers the advantage of a small background, at the price of a low signal production rate. Three classes of final states are available, depending on the \( \tau \)-lepton decay: lepton-lepton (ll), lepton-hadron (lh), and hadron-hadron (hh). ATLAS has studied the final states ll, produced in association with at least one high-\( p_T \) jet, and lh [8, 9]. The most important backgrounds are represented by the production of \( W, Z \rightarrow \text{leptons+jets}, \ Z \rightarrow \tau^+\tau^- \) (largely irreducible), dibosons, tt, single top and jets. The analysis is based on the selection of of high-\( p_T \) leptons and of at least one jet. The collinear approximation [19] (missing mass calculator [20]) is adopted to reconstruct the tau momentum in the ll(lh) decay mode. The \( \tau\tau \) system invariant mass is studied to search for the Higgs signal.

The background contamination in the selected event sample is evaluated with methods based on measurements from data, or on predictions from Monte Carlo simulation. The overall uncertainty on the background level in the ll final state is 8\%, while for lh is 19\%.

No event excess is found, and an exclusion limit on the Higgs production cross section is set, see Figure 3(b).
The "transverse mass" $m_T$, defined as $m_T = \sqrt{(E_T^{miss} + \sum E_T^{jet})^2 - (\sum \mathbf{p}_T^{jet} + \mathbf{p}_T^{miss})^2}$, where $\mathbf{p}_T^{jet}$ is the transverse momentum of the dilepton system and $E_T^{miss}$ is its associated energy, is reconstructed and used for the final selection: for a given Higgs mass hypothesis $m_H$, events satisfying the condition $0.75 < m_H < 200$ GeV are accepted. Figure 4(a) shows for the 0-jet selection, the distribution of the lepton-lepton azimuthal opening angle. Figure 4(b) shows the $m_T$ distribution for the 1-jet selection.
It is important to estimate the background contamination in the signal region by measurements performed with data control samples. In the analysis presented in this document, the three largest background contributions to this channel, from $WW^{(*)}$, top and $W$+jets, are evaluated using the collision data. For the remaining smaller background contributions, Monte Carlo predictions are used. The number of events counted in control regions enriched by a given SM process are propagated to the signal region through an extrapolation factor evaluated with MC samples. Extrapolation factors are evaluated for $WW^{(*)}$ and top processes, while the $W$+jet contamination is fully measured in data. Table reports the number of event expected from Standard Model processes, as well as from a Higgs boson with mass of $m_H=150$ GeV. These numbers are compared with the observed number of event for each category. The main uncertainties on the $WW^{(*)}$ and top quark production background contribution to the selected events are due to the accuracy of the extrapolation of their measurement from the control regions to the signal region. They account for the effects to the the limited knowledge of the JES, b-tagging efficiency, as well as the renormalization and factorization scales, and the parton distribution functions associated to the theory models used to perform these extrapolations. The uncertainty on the Higgs boson signal yield is 5% in the 0-jet bin and 12% in the 1-jet bin.

No significant excess of events if found, and therefore an exclusion limit on the production cross section of a Standard Model-like Higgs boson is set.

Figure shows the observed and expected limits at 95% C.L. for the combined 0-jet and 1-jet analyses as a function of the Higgs boson mass. A SM Higgs boson is excluded in the mass interval $154 < m_H < 186$ GeV, while the expected Higgs boson exclusion mass interval is $135 < m_H < 196$ GeV. The largest observed difference between observed and expectd limit is less than $2\sigma$. 
Table 2. The number of background events, in the 0-jet and 1-jet bins, expected from Standard Model processes, observed in the data, and expected from the production of a Higgs boson with $m_H = 150$ GeV, using an integrated luminosity of 1.7 fb$^{-1}$. The uncertainties shown are the combination of the statistical and all systematic uncertainties, including the ones from the background extrapolations from control to signal regions [10].

| category | $WW$ | $tt$ | total SM back. | Data | Higgs |
|----------|------|-----|----------------|------|-------|
| 0-jet    | 43±6 | 2.2±1.4 | 53±9 | 70 | 34±7 |
| 1-jet    | 10±2 | 6.9±1.9 | 23±4 | 23 | 12±3 |

Figure 4. The expected (dashed) and observed (solid) 95% C.L. upper limits on the production cross section from $H \rightarrow WW^*(\rightarrow l\nu l\nu)$ normalized to the Standard Model prediction, as a function of the Higgs boson mass. The observed limits at neighboring mass points are highly correlated due to the limited mass resolution of this final state. The bands indicate the 1σ and 2σ uncertainty regions on the expected limit. The jump visible at $m_H=220$ GeV is due to the change of the selection criteria at that mass point [10].

5. $H \rightarrow ZZ \rightarrow ll\nu\nu$ and $H \rightarrow ZZ \rightarrow llqq$

The decay $H \rightarrow ZZ \rightarrow ll\nu\nu$ is characterized by a final state where two leptons are produced in association of large transverse missing energy. This decay mode offers a significant branching fraction in combination with a good separation from background processes. These processes are mainly the irreducible diboson production $WW$, $WZ$ and $ZZ$, plus the reducible background processes represented by top quark final states, as well as $W, Z$+jets. The analysis proceeds with the selection of two isolated same-flavour opposite charge high-$p_T$ leptons whose invariant mass is consistent with the $Z$-mass, and large $E_T^{miss}$. Topological cuts are applied to suppress the $W, Z$+jets background. Finally the transverse mass distribution $m_T$, defined as:

$$m_T^2 = \left( \sqrt{m_Z^2 + |p_T^l|^2} + \sqrt{m_Z^2 + |p_T^{miss}|^2} \right)^2 + (p_T^l + p_T^{miss})^2$$  \hspace{1cm} (1)$$

is studied to search for contributions from the production and decay of the SM Higgs boson ($p_T^{miss}$ is the missing transverse energy vector).

The systematic uncertainties include experimental uncertainties related to the calibration and reconstruction efficiencies of electrons, muons, jets, and b-jets that are propa-
Aleandro Nisati, ATLAS Coll.

...gated also the reconstruction of $E_T^{miss}$. Uncertainties relative to the Higgs signal yield prediction (about 12% for the gluon-gluon production and 4% for the VBF) as well as to the ZZ background (11%), have been also taken into account.

The observed $m_T$ distribution is consistent with the expectations from Standard Model processes. Exclusion limits at 95% C.L. have been set as a function of the Higgs boson mass. The results are shown in Figure 5(a). A Standard Model Higgs boson with mass in the region $340 < m_H < 450$ GeV is excluded. The expected limit is lowest around $m_H = 380$ GeV where it is 1.1 times the cross section predicted by the SM. The observed and expected limits agree within 2σ over the entire mass range. The details of this analysis are in [12].

Another channel important for high-mass SM Higgs boson searches is the decay $H \rightarrow ZZ \rightarrow ll\ell\ell$, also characterized by a large branching fraction. The event selection is based on the reconstruction of final states with two same flavour opposite charge high-$p_T$ leptons, whose invariant mass is consistent with the $Z$ boson mass $m_Z$, in association with two high-$p_T$ jets again with an invariant mass consistent with $m_Z$, and no significant transverse missing energy. The distribution studied for the Higgs boson search is obviously the two-lepton and two-jet system invariant mass. This distribution is studied also for events with both jets b-tagged [18]. The dominant background is the irreducible $ZZ$ production, the reducible $WZ$, $Z,W+jets$ and QCD jets. The Higgs boson signal would appear as a bump on top of the expected background, see Figure 5(b). No significant excess is observed, and therefore 95% C.L. production cross section exclusion limits are set. A production cross section about 1.7 times the one predicted by the SM is excluded for $m_H \sim 360$ GeV. The expected limit is between 2.7 and 9 the SM cross section in the mass range 200 to 600 GeV. The details of this analysis are in [13].

6. $H \rightarrow ZZ^{(*)} \rightarrow lll$

Three distinct channels are studied in this analysis: $H \rightarrow ZZ^{(*)} \rightarrow e^+e^-e^+e^-$, $\mu^+\mu^-\mu^+\mu^-$, $e^+e^-\mu^+\mu^-$. The production of SM $ZZ^{(*)}$ dibosons represents the irreducible background. Processes such as $Z+jets$ (in particular $Zbb$) and $tt$, where at least
two fake/non-prompt leptons are reconstructed from jets or heavy quark semi-leptonic decays, represent the more important reducible backgrounds to these final states. Data have been selected using single-lepton triggers. In the offline analysis, events with two pairs of same-flavour opposite-sign isolated leptons are selected. Each lepton must have $p_T > 7$ GeV; electrons (muons) should lie in the region $|\eta| < 2.47 (2.50)$. The electron $p_T$ threshold is increased to 15 GeV if the associated pseudorapidity is between $1.37 < |\eta| < 1.52$.

At least two leptons must have $p_T > 20$ GeV. The two lowest $p_T$ leptons in events with the 4-lepton invariant mass of $m_{4l} < 190$ GeV are required to be tightly associated to the primary vertex with cuts to the impact parameter significance (defined as the transverse impact parameter divided by its uncertainty).

The invariant mass $m_{12}$ of the lepton pair closest to the Z mass must fulfill $|m_{12} - m_Z| < 15$ GeV. The invariant mass $m_{34}$ of the other pair is required to be lower than 115 GeV and greater than a threshold depending on the reconstructed 4-lepton mass. The full-width half-maximum (FWHM) of the reconstructed Higgs particle, expected to be dominated by the experimental mass resolution for low $m_H$ values, varies between 4.5 (4\mu) GeV and 6.5 GeV (4\sigma) for $m_H = 130$ GeV. At high $m_H$ the reconstructed width is dominated by the intrinsic width (e.g. FWHM=35 GeV for $m_H=400$ GeV).

The expected contribution from SM background is estimated with Monte Carlo simulation, except the Z+jets process whose contribution is measured in data. The irreducible ZZ($^*$) process is predicted with an uncertainty of 15% (includes both quark-quark, quark-gluon and gluon-gluon scattering), while the top estimation, predicted with an uncertainty of 10%, is validated with data control samples. The Z+jet(s) contribution is evaluated starting from a sample of Z+lepton-pair selected with no isolation or impact parameter requirements. This yield is then extrapolated to the signal region applying reduction factors estimated with MC simulation. The uncertainty on the event contamination from this source varies in the range 20% to 40%.

Figure 6. (a) Invariant mass distribution for the selected 4-lepton event candidates. The data are compared to the background expectations. (b) The expected (dashed) and observed (full line) 95% C.L. upper limits on the SM Higgs boson production cross section, normalized to the SM prediction, as a function of its mass. Green and yellow bands indicate the fluctuations at 1\sigma and 2\sigma around the value of the median [11].

Figure 6(a) shows the distribution of the invariant mass of the selected candidates, compared to the expected contribution from SM processes. No significant excess of events has been found with respect to the SM prediction. Figure 6(b) shows the 95% C.L. exclusion
limit on the production cross section for the SM Higgs boson as a function of its mass. Details on the number of candidates selected in data and MC are illustrated in Table 3. A SM Higgs boson with mass $191 < m_H < 197$, $199 < m_H < 200$ and $214 < m_H < 224$ GeV is excluded. The observed limits are consistent within less than 2σ with the expected ones. More details on this study are available in the paper recently submitted [11].

| sample | $4\mu$ (L=2.28 fb$^{-1}$) | $2e2\mu$ (L=1.96 fb$^{-1}$) | $4e$ (L=1.98 fb$^{-1}$) |
|--------|----------------|----------------------------|----------------|
| observed | 12 | 9 | 6 |
| expected | 8.8±1.2 | 11.1±1.4 | 4.32±0.52 |

Table 3. The observed and expected number of events after full selection by the analysis for the $H \rightarrow ZZ^{(*)} \rightarrow 4l$ search [11].

7. Overall SM Higgs Combination

Figure 7. (a) The expected (dashed) and observed (solid) cross section 95% exclusions limits for the individual search channels, normalised to the Standard Model Higgs boson cross section, as functions of the Higgs boson mass. (b) The combined upper limit on the Standard Model Higgs boson production cross section divided by the Standard Model expectation as a function of $m_H$ is indicated by the solid line [21].

All channels presented in this paper are combined with a statistical procedure publicly available [22], which is again based on the modified frequentist method $CL_s$ [16]. The profile likelihood ratio is used as a test statistics, whose distribution function is obtained either with toy Monte Carlo pseudo-experiments, or using asymptotic analytic expressions [17]. The uncertainties of correlated experimental uncertainties (JES, luminosity,...), across different Higgs channels, are taken into account. A careful treatment of theory uncertainties is also made, paying again attention to those that are correlated, as for example the uncertainty on the Higgs boson production cross section [15]. Figure 7(a) summarizes the individual standalone exclusion limits associated to the Higgs boson channels discussed in this paper. The result of the combination of these results is shown in figure Figure 7(b). The production of a Standard Model Higgs boson is excluded at 95% C.L. in the mass regions $144 < m_H < 232$ GeV, $256 < m_H < 282$ GeV, and $296 < m_H < 466$ GeV. Moreover, the mass regions between 160 and 220 GeV, and between 300 420 GeV, are excluded at least with 99
Aleandro Nisati, ATLAS Coll.

The exclusion limit in the mass region $110 < m_H < 135$ GeV is given mainly from the combination of the $H \rightarrow \gamma\gamma$ and $H \rightarrow WW^{(*)} \rightarrow l\nu l\nu$ decay channels. For mass values of $m_H$ up to 180 GeV, the limit is dominated by the $H \rightarrow WW^{(*)} \rightarrow l\nu l\nu$ decay, while the channels $H \rightarrow ZZ \rightarrow 4l$ and $H \rightarrow ZZ \rightarrow ll\nu\nu$ dominate the exclusion limit for $m_H > 180$ GeV.

The expected exclusion covers Standard Model Higgs boson mass range from 131 GeV to 450 GeV. The observed limit is in very good agreement with the background only expected limit over most of the studied mass range, except in the low mass region $130 < m_H < 170$ GeV where the observed limit is consistent with 2$\sigma$ with the one expected in the hypothesis of no signal. This is mainly due to the results coming from the search for $H \rightarrow WW^{(*)} \rightarrow l\nu l\nu$ production. More details on this combination are available in this ATLAS public note [21].

The full data set collected during the 2011 run, more than 5 fb$^{-1}$ for ATLAS and CMS, will definitely help to better understand the data, improve the physics analyses and to increase further the sensitivity to the Higgs boson search to a wider mass interval.
