In non-central collisions between ultra-relativistic heavy ions, the freeze-out distribution is anisotropic, and its major longitudinal axis may be tilted away from the beam direction. The shape and orientation of this distribution are particularly interesting, as they provide a snapshot of the evolving source and reflect the space-time aspect of anisotropic flow. Experimentally, this information is extracted by measuring pion HBT radii as a function of angle with respect to the reaction plane. Existing formulae relating the oscillations of the radii and the freezeout anisotropy are in principle only valid for Gaussian sources with no collective flow. With a realistic transport model of the collision, which generates flow and non-Gaussian sources, we find that these formulae approximately reflect the anisotropy of the freezeout distribution.

I. INTRODUCTION

Femtoscopic intensity interferometry measurements use two-particle correlation functions to probe the space-time substructure of the system generated in heavy ion collisions, at the femtometer scale. At relativistic collision energies, extensive systematic studies have mapped out this substructure as a function of transverse momentum ($p_T$), rapidity ($y$), collision energy ($\sqrt{s_{NN}}$) and the mass of the two correlated particles; see [1] for a recent review. These measurements probe the space-time geometry of the freezeout distribution—the distribution of last-scattering points of the particles. In addition to the source size and lifetime at freezeout, the momentum-dependence of the femtoscopic scales reveal the coordinate-space aspects of collective motion—“flow.”

It has long been recognized that measurements relative to the direction of the impact parameter of the collision are more sensitive to important underlying physics of the system, than are angle-integrated measurements. The azimuthal dependence of particle yields and spectra—often called “directed” and “elliptical flow”—are extensively used to extract the QCD equation of state (EoS) and transport coefficients of the quark-gluon plasma such as viscosity [2, 3]. On the other hand, azimuthally-integrated $p_T$ spectra can flag the existence of collective behavior, but are not as discriminating between different models producing such behavior [e.g. 4, 5]. Similarly, the azimuthal dependence of jet quenching is a more discriminating probe of partonic energy loss, than azimuthally-integrated measurements [6, 7].

It is possible that azimuthally-differential analysis might yield a similar improvement in sensitivity of femtoscopy. Only a few measurements of femtoscopic pion correlations relative to the impact parameter have been reported [9–11], though an extensive energy-dependence of these measurements is underway at RHIC [12].

Most femtoscopic analyses of pion correlations extract so-called “HBT radii” (c.f. discussion in [1]) which fully describe the emission distribution only if it is purely Gaussian and features no collective motion. Strictly speaking, neither of these conditions characterize heavy ion collisions, and there has been considerable activity in measuring the non-Gaussian features of the source via “imaging” techniques [13, 14] that fit the source with a sum of spline functions. Large non-Gaussian tails are mostly explained by long-lived resonance production [15].

Gaussian HBT radii seek to capture the bulk scales of particular interest; several studies exist, testing the correspondence between HBT radii and the source scales of non-Gaussian, flowing distributions from cascade calculations [16, 17] and blast-wave and hydrodynamical models [18].

Moving beyond HBT radii themselves, which characterize the geometry only of subsets (“homogeneity regions” [19]) of the overall source, one is interested in the shape and orientation of the emission region as a whole. Retiere and Lisa have proposed [20] a formula connecting the azimuthal oscillations of HBT radii with the transverse anisotropic shape of the source. Here, we follow the same line and propose a formula for the tilt of the source relative to the beam direction. Both of these formulae are strictly valid only for Gaussian, non-flowing sources. In this paper, we test these formulae in the context of a realistic transport model featuring non-Gaussian freezeout distributions and strong flow. We find reasonable consistency between the source eccentricity and tilt as extracted directly from the space-time freezeout coordinates, and the same quantities estimated with the formulae. The discrepancy between the two provides an estimate of the systematic uncertainty one expects, when using azimuthally-differential pion correlation measurements to extract the underlying source shape and orientation.

In section II, we define the formalism and the connection between HBT radii and an anisotropic but simplified static Gaussian source. There, we present formulae connecting measurable quantities to the interesting features of the geometry. In section III a realistic transport model (UrQMD) is used to generate a freezeout distribution featuring non-Gaussian geometry and strong collective flow. We discuss the non-trivial anisotropies of the distribution and the relationship between regions of homogeneity [21] and the “whole” source of emission points. In section IV we simulate an experimental analysis, using the UrQMD-generated distributions. We build two-pion correlation functions and
use the formulae presented in section II to estimate the source anisotropies. The calculations are compared to reported experimental results from Au+Au collisions at \( \sqrt{s_{NN}} = 3.84 \) GeV, and predictions are given for heavy ion collisions at \( \sqrt{s_{NN}} = 30 \) GeV, relevant for FAIR and the RHIC energy scan. In section V we summarize.

II. HBT RADIi AND THEIR CONNECTION TO THE UNDERLYING SOURCE

Femtoscopic two-particle correlation functions as a function of the relative momentum \( q = p_1 - p_2 \) are often fitted in terms of Gaussian HBT radii \( R_{i,j}^2 \)

\[
C(q) = 1 + \lambda \exp \left( - \sum_{i,j=0,x,y,z} q_{ij} R_{i,j}^2 \right). \tag{1}
\]

Indices \( i \) and \( j \) indicate the components of the \( q \) vector in the so-called Bertsch-Pratt “out-side-long” coordinate system \([22–24]\). Here, “out” points along the direction of the pair transverse momentum, and “long” points along the direction of motion of one of the incoming nuclei, say, in the direction of Au ions in the yellow ring of RHIC. We shall call this the “yellow nucleus” and its colliding partner the “blue nucleus.” (We return to this arbitrary designation soon.) The “side” direction is given by the cross-product of “out” with “long.” It is worthwhile to point out that, while one may simultaneously flip the signs of all components of \( q \) by swapping the designation of particles 1 and 2, the correlation function depends only on even-order products of \( q \)’s components; these products have meaningful sign.

We begin by considering a simple source of midrapidity pions which is a Gaussian ellipsoid in space and time, with the major axis of the ellipse tilted with respect to the beam direction, as sketched in Figure 1. The distribution is characterized by five parameters: a temporal scale, three spatial scales and a tilt angle

\[
f(x,y,z) \sim \exp \left( -\frac{(x \cos \theta_z - z \sin \theta_z)^2}{2\sigma_x^2} - \frac{y^2}{2\sigma_y^2} - \frac{(x \sin \theta_z + z \cos \theta_z)^2}{2\sigma_z^2} - \frac{t^2}{2\sigma_t^2} \right). \tag{2}
\]

where the primes on \( \sigma_{x'z} \) and \( \sigma_{y'z} \) signify that these correspond to principle axes of the ellipse.

Its transverse eccentricity about its (tilted) major axis is defined as

\[
\epsilon' \equiv \frac{\sigma_y^2 - \sigma_{y'z}^2}{\sigma_y^2 + \sigma_{y'z}^2} \tag{3}
\]

If \( \theta_z = 0 \) and \( \sigma_x = \sigma_y \equiv \sigma_{\perp} \) (or equivalently in an azimuthally-integrated analysis), only three parameters characterize the source, and the HBT radii are given by

\[
R_x^2 = \sigma_z^2,
R_y^2 = \sigma_z^2 + \beta_z^2 \sigma_{\perp}^2,
R_z^2 = \sigma_z^2 + \beta_{\perp}^2 \sigma_{\perp}^2, \tag{4}
\]

where \( \beta_{\perp} \) and \( \beta_z \) are the transverse and longitudinal velocities of the pion pair. “Cross-term” radii \( R_{i\neq j}^2 \) vanish by symmetry \([25,26]\).

For the more general case, there are six HBT radii, and they depend on the azimuthal angle \( \phi \). This angle is meaningfully defined over the range \([0,2\pi]\) about the beam direction relative the impact parameter, which is defined as the direction perpendicular to the beam, pointing from the yellow nucleus to the blue one. Swapping the designations of the “yellow” and “blue” nuclei reverses the direction of the impact parameter (\( x \) direction); however, it also reverses the “long” (\( z \) direction), defined earlier. Hence, the sense of the tilt \( \theta_z \) is well-defined; a source with positive tilt features a positive spatial \( x \) – \( z \) correlation, as shown in Figure 1. Experimental measurement of the sense of the tilt \( \theta_z \) requires measuring the direction of the impact parameter, for example through directed flow of net baryons at forward rapidity.

The HBT radii, measured as a function of angle \( \phi \) relative to the beam axis, are driven by source widths \( \sigma_x, \sigma_y, \sigma_z \), rather than \( \sigma_{x'} \), \( \sigma_{y'} \), \( \sigma_{z'} \). The relationships between these widths are given by

\[
\sigma_{x'}^2 = \sigma_z^2 \cos^2 \theta_z + \sigma_y^2 \sin^2 \theta_z + \sigma_{z'}^2 \sin 2\theta_z,
\sigma_{y'}^2 = \sigma_z^2 \sin^2 \theta_z + \sigma_y^2 \cos^2 \theta_z - \sigma_{z'}^2 \sin 2\theta_z, \tag{5}
\]

where \( \sigma_x^2 \) is the covariance between \( x \) and \( z \) in the source function; see \([25]\) for details.
The HBT radii are related to these widths as \[25\]
\[
R_2^2(\phi) = \frac{1}{2} (\sigma^2 + \sigma^2_t) + \frac{1}{4} (\sigma^2 - \sigma^2_t) \cos 2\phi,
\]
\[
R_0^2(\phi) = \frac{1}{2} (\sigma^2 + \sigma^2_t) - \frac{1}{2} (\sigma^2 - \sigma^2_t) \cos 2\phi + \beta^2 \sigma^2_t,
\]
\[
R_{\alpha\beta}^2(\phi) = \frac{1}{2} (\sigma^2 - \sigma^2_t) \sin 2\phi.
\]
\[
R_{\alpha\beta}^2(\phi) = \sigma^2_{\alpha\beta} \sin \phi,
\]
\[
R_{\alpha\beta}^2(\phi) = -\sigma^2_{\alpha\beta} \cos \phi.
\]

In analogy with Equation [3] we identify the eccentricity of the source around the beam axis as
\[
\varepsilon \equiv \frac{\sigma^2_{\alpha\beta} - \sigma^2_{\alpha\alpha}}{\sigma^2_{\alpha\alpha} + \sigma^2_{\alpha\alpha}}.
\]

Equations [5] express the explicit \(\phi\)-dependence of the HBT radii for a non-flowing source; all other variables in the equations are constants, for a non-flowing source. For a source with flow, the constants, e.g. \(\sigma\), may themselves depend on \(\phi\). In this case, our equations will be violated; below, we quantify this violation and its effect on the extraction of \(\theta_a\) and \(\varepsilon\).

Experimentally, one measures the squared HBT radii and calculates the Fourier coefficients quantifying their azimuthal dependence, per [20][26]
\[
R_2^2(\phi) = R_{2,0}^2 + 2 \sum_{n=2,4,6,...} R_{2,n}^2 \cos(n\phi),
\]
\[
R_0^2(\phi) = R_{2,0}^2 + 2 \sum_{n=2,4,6,...} R_{2,n}^2 \cos(n\phi),
\]
\[
R_{\alpha\beta}^2(\phi) = 2 \sum_{n=2,4,6,...} R_{\alpha\beta,n}^2 \sin(n\phi),
\]
\[
R_{\alpha\beta}^2(\phi) = R_{\alpha\beta,0}^2 + 2 \sum_{n=2,4,6,...} R_{\alpha\beta,n}^2 \sin(n\phi),
\]
\[
R_{\alpha\beta}^2(\phi) = 2 \sum_{n=1,3,5,...} R_{\alpha\beta,n}^2 \cos \phi,
\]
\[
R_{\alpha\beta}^2(\phi) = 2 \sum_{n=1,3,5,...} R_{\alpha\beta,n}^2 \sin \phi.
\]

Equivalently,
\[
R_{\mu,\nu}^2(p_T) = \begin{cases} (R_2^2(p_T, \phi) \cos(n\phi)) & (\mu = o, s, l, o l) \\ (R_2^2(p_T, \phi) \sin(n\phi)) & (\mu = o s, s l) \end{cases}.
\]

In our no-flow Gaussian model, then, the source geometry and orientation are extracted from the Fourier coefficients. Identifying the tilt angle requires [25][26] measuring HBT relative to the first-order reaction plane [3]. Published results from the STAR [10] and CERES [11] collaborations use only the 2nd-order plane and so report the source eccentricity only about the beam axis. (Efforts to perform the analysis relative to the first-order plane are underway at RHIC [12].) In this case [20]
\[
\varepsilon = 2 \frac{R_{s,2}^2}{R_{s,0}^2}.
\]

For the moment, we ignore the tildes above the \(n \neq 1\) Fourier coefficients here and below. They represent a trivial finite-binning correction discussed later in section [IV].

If the first-order plane is identified, first-order azimuthal oscillations in \(R_{s,0}^2\) and \(R_{s,2}^2\) are measurable. In this case one obtains the tilt angle according to [25]
\[
\theta_a = \frac{1}{2} \tan^{-1}\left(\frac{-4 R_{s,1}^2}{R_{s,0}^2 - R_{s,0}^2 + 2 R_{s,2}^2}\right).
\]

The transverse eccentricity in the “natural” frame tilted relative to the beam axis is
\[
\varepsilon' = \frac{2 R_{s,2}^2 (1 + \cos^2 \theta_a) + (R_{s,0}^2 - R_{s,0}^2) \sin^2 \theta_a - 2 R_{s,1}^2 \sin 2\theta_a}{R_{s,0}^2 (1 + \cos^2 \theta_a) + (2 R_{s,2}^2 + R_{s,0}^2) \sin^2 \theta_a + 2 R_{s,1}^2 \sin 2\theta_a}
\]

III. FREEZEOUT DISTRIBUTIONS FROM A MORE REALISTIC MODEL

Our simple model of the emission function given in equation [2] is unrealistic in at least two ways. Firstly, while realistic emission functions are often roughly Gaussian, they are never perfectly so; in this case, the two-pion correlation function is likewise non-Gaussian. Extracting Gaussian HBT errors through fits with equation [1] then, could in principle generate considerable mis-representation of the emission function.

The second over-simplification of the source discussed above is its lack of collective flow, which generates correlations between a particle’s emission position and its momentum [19]. For example, an explosively flowing source will boost particles emitted from its right side, towards the right. The freezeout distribution of particles with a given momentum vector is known as the region of homogeneity for that momentum vector. In principle, the homogeneity regions for different azimuthal angles might be completely disjoint and unrelated, obviously invalidating equations [6][10][11] and [12]. In practice, the homogeneity regions in blast-wave models [20] or hydrodynamic simulations [27] are naturally related. For boost-invariant sources, equation [10] is estimated to be good to \(~30\%) in these models [20].

While blast-wave and boost-invariant hydro models do feature non-Gaussian sources and collective flow, they are still simplistic. Firstly, any boost-invariant model by definition has no tilt relative to the beam axis; thus they are unable to access physics associated with \(\theta_a\). Secondly, they typically use the Cooper-Frye formula to model particle freezeout from a calculated or parameterized hypersurface; while momentum-space observables (e.g. \(v_2\)) may be insensitive to this procedure, interferometry is known to be quite sensitive to the freezeout procedure.

In this section, we use the Ultra-Relativistic Quantum Molecular Dynamics Model (UrQMD 3.3)[40] to generate a realistic freeze-out distribution with fully three-dimensional dynamics [28][29]. UrQMD is a covariant transport approach to simulate the interactions between hadrons and nuclei up to relativistic energies. It is based on the propagation of nucleons and mesons accompanied by string degrees of freedom with interaction probabilities according to measured and calculated cross sections for the elementary reactions. Hard scatterings
FIG. 2: (color online) Pion emission points from UrQMD simulations of Au+Au collisions with collision energy $\sqrt{s_{NN}} = 3.84$ GeV (corresponding to a 6 AGeV beam incident on a fixed target) and impact parameter $b = 4 - 8$ fm. Colored contours (identical for the three panels) show the emission point density of all pions with $p_T < 0.4$ GeV/c. Black contours in the upper, middle and lower panels indicate the density of emission points for pions with $\phi = \left[-\frac{\pi}{8}, \frac{\pi}{8}\right]$, $\left[\frac{3\pi}{8}, \frac{5\pi}{8}\right]$, and $\left[\frac{7\pi}{8}, \frac{9\pi}{8}\right]$, respectively.

with large momentum transfer are treated via PYTHIA. For detailed comparisons of this version to experimental data, the reader is referred to [30]. Previous HBT studies with UrQMD have been reported in [31–34].

In UrQMD, the freeze-out space-time point is naturally defined as the last hard interaction of a particle. The freezeout distribution of pions from $\sqrt{s_{NN}} = 3.84$ GeV Au+Au collisions with impact parameter $b = 4 - 8$ fm in the reaction plane ($x-z$ plane) is shown in figure 3. The source has an obvious tilt structure relative to the beam axis. We use the parameterization of equation 2 to fit the three-dimensional freezeout distribution for all pions with $p_T < 400$ MeV/c and $|y| < 0.6$—not only those at a given angle $\phi$. From this direct analysis of the freezeout coordinates—obviously not possible in experiment—we find the parameters listed in the third column of table I. It is clear from figure 3 that $x-z$ correlation in the freezeout distribution has structure that cannot be captured in a single tilt number; indeed, the tilt is scale-dependent, growing as one focuses on the peak of the distribution. This “twist” feature, which has been observed in simulations before [25], might be physically interesting and experimentally accessible; we leave exploration of this effect for a future work. For the purpose of this work, we identify a range of tilts arising from fitting equation 2 to the distribution and varying the fit range in coordinate space from $10 \, \text{fm} < \Delta x, \Delta y, \Delta z < 40 \, \text{fm}$. This leads to the range shown in the left column of table I.

Dynamics naturally leads to a strong correlation between a particle’s final momentum and the freezeout position; homogeneity regions are naturally reflected in the final state. Figure 2 shows homogeneity regions from UrQMD in the $x-y$ plane for particles emitted at three azimuthal angles. The homogeneity region for particles emitted at a given angle $\phi$ clearly differs from that for particles emitted at $\phi_2 \neq \phi_1$. Thus, in addition to the explicit $\phi$-dependence of the HBT radii seen in equations (6), there is an additional implicit dependence [35–38]. HBT radii measured at a given momentum vector $(\phi, p_T, y)$ probe only the geometry of the homogeneity region for that momentum vector. A priori, it is far from clear that equations (10, 11 and 12) which attempt to relate HBT ra-
radius oscillations to the geometry of the “whole” source, will prove good approximations.

In the next section, we test these relations—true for the simplest toy model of Equation 2—with UrQMD-generated freezeout distributions.

IV. HBT RADIi AND ANISOTROPY PARAMETERS FROM URQMD-GENERATED CORRELATION FUNCTIONS

We start by generating two-pion correlation functions, analogous to those measured experimentally, from UrQMD events. We will then proceed to fit these correlation functions with the Gaussian ansatz of equation 1 as is done in experimental analysis. Finally, we extract Fourier coefficients characterizing the oscillations of the HBT radii with angle; from these we extract the source anisotropy parameters that would be obtained in an experiment.

To simulate experimental conditions, two-pion correlation functions were constructed from the UrQMD events using the so-called weighting method [47]. In this method, pairs of identical pions are selected according to a Monte Carlo algorithm; the correlation function in a given \( q_0, q_s, q_l \) bin is equal to the pair-wise average of the squared two-pion squared wavefunction. Considering only quantum symmetrization effects, the correlation function is computed as

\[
C(q_0, q_s, q_l; \phi) = \langle 1 + \cos(-q^\mu \Delta r_\mu) \rangle_{q}, \tag{13}
\]

where \( q = p_1 - p_2 \) is the relative momentum and \( \Delta r \) is the space-time separation of the particles at freezeout.

As explicitly denoted in equation 13, the correlation functions were generated for 8 45°-wide bins in pair angle \( \phi \equiv \angle(K_T, \hat{b}) \), where \( K_T \equiv (\vec{p}_{T,1} + \vec{p}_{T,2})/2 \) is the average transverse momentum vector of the pair. Hence, for \( -\frac{\pi}{2} < \phi < \frac{\pi}{2} \) \((\frac{3\pi}{2} < \phi < \frac{5\pi}{2})\), pions from sub-region indicated by the black contours in the top (bottom) panel of figure 2 are used to construct the correlation function.

In figure 3 are plotted, for each bin in \( \phi \), two-dimensional slices of the three-dimensional correlation function in the \( q_0 - q_s, q_s - q_l \) and \( q_l - q_0 \) planes; in each case the unploted relative momentum component \( q_i < 4 \text{ MeV/c} \). For a representative \( \phi \) bin, one-dimensional slices of the correlation function in the out, side, and long directions are shown in Figure 4. Most femtoscopic correlation analyses focus on the one-dimensional projections, since the correlation in three-dimensional space factorizes; that is, there is no covariance between components \( q_i \) and \( q_{j \neq i} \) in the correlation function. This is not the case when the analysis is performed differentially in \( \phi \) [9, 25, 26, 35–38], as is clear from the tilted structures in \( \vec{q} \)-space seen in figure 4. These tilts in the individual correlation functions in \( \vec{q} \)-space for a given angular selection in \( \vec{K} \) are not to be confused with the overall spatial tilt of the source sketched in figure 1.

As in an experimental analysis, the correlation functions are fitted with the Gaussian functional form of equation 1. Two- and one-dimensional slices of these fits are superimposed on the correlation functions in figures 4 and 5. The six resulting HBT radii are plotted as a function of \( \phi \) on figure 6. As in a standard azimuthally-integrated analysis, the “diagonal” radii \( R_{j,j}^2 \) are driven by the width of the correlation function in the direction \( j \). The “cross-term” radii \( R_{i,j\neq i}^2 \) quantify the correlations between \( \vec{q} \) components—the tilts of the correlation function; e.g. the \( \phi \)-dependence of the tilt of the corre-

![Figure 4: (color online) Pion correlation functions from Au+Au collisions with collision energy \( \sqrt{s_{NN}} = 3.84 \text{ GeV} \) and (corresponding to a 6 AGeV beam incident on a fixed target) and impact parameter \( b = 4 - 8 \text{ fm} \), as calculated with the UrQMD model. Projections in the \( q_0 - q_s \) (left column), \( q_s - q_l \) (middle) and \( q_l - q_0 \) spaces are made, with the unploted \( \vec{q} \)-component smaller than 4 MeV/c. From the ones extracted from the binned radii by

\[ R_{\mu,n}^2 = \frac{n \Delta \phi / 2}{\sin (n \Delta \phi / 2)} R_{\mu,n}^2. \]  

(14)

For our 45°-wide bins, \( R_{\mu,1}^2 = 1.026 R_{\mu,1}^2 \) and \( R_{\mu,2}^2 = 1.111 R_{\mu,2}^2 \). These binning-corrected Fourier coefficients are used in equations 10-12 [48].

As in most experimental analyses, the correlation functions from UrQMD simulations are not purely Gaussian, since the source itself is not Gaussian in coordinate space, due to space-momentum correlations (flow), resonance contributions, etc. Of special interest for the present study is the additional fact that the source is not characterized by a tilt angle independent of spatial scale—the “twist” discussed in section III. Following a standard experimental approach [e.g. 59], we perform a fit-range study, in which we vary the range in \( q_0, q_s, q_l \), over which we perform the fit with equation 1. In particular, we fit the correlation functions in the range \( -q_{\text{max}} < q_0, q_s, q_l < q_{\text{max}} \) for \( q_{\text{max}} = 60 - 150 \text{ MeV/c} \). The resulting anisotropy parameters for \( \sqrt{s_{\text{NN}}} = 3.84 \text{ GeV} \) collisions, calculated according to equations 10-12 are shown on figure 8. The dependence of \( \theta_3 \) on \( q_{\text{max}} \) is readily understood. Large values of \( q \) probe smaller values of coordinate space; thus, as \( q_{\text{max}} \) is increased, the fit is increasingly sensitive to the large tilt structure seen at small scales in figure 3. Figure 8, then, is itself a measure of the “twist” structure in coordinate space, though there may be more sophisticated ones. For our purposes, however, we take the variation of the anisotropy parameters plotted in figure 8 to define a range of values one might expect from an experimental study. Since a typical experimental analysis would fit at least out to 100 MeV/c (in order to include all of the peak signal), the value ranges listed in the fourth column of table 1 correspond to 100 MeV/c < \( q_{\text{max}} < 150 \text{ MeV/c} \).

The agreement with the parameters extracted via direct analysis of the UrQMD freezeout coordinates is fair; and we discuss this further in the next section.

The fifth column in table 1 lists the anisotropy parameters based on HBT radii measured by the E895 collaboration in a fixed-target experiment at \( E_{\text{beam}} = 6 \text{ AGeV} \) [9].
 clarification needed.

TABLE I: Source anisotropy parameters, for Au+Au collisions at two collision energies, with $b = 4 - 8$ fm for pions with $p_T < 0.6$ GeV/c, and $|y| < 0.6$. Impact parameter and momentum cuts were selected to match published data from the E895 collaboration [9]. Third column: estimates from a Gaussian fit (equation 2) to the freezeout distribution from UrQMD events. Fourth column: estimates using equations 10-12 on the azimuthal oscillations of HBT radii from UrQMD events. Fifth column: same as column four, but using experimental data from E895. Experimental data at 7.7 GeV will be analyzed at FAIR and RHIC.

V. DISCUSSION AND SUMMARY

The connection between anisotropic particle emission distributions and femtoscopic correlation functions has been discussed in detail. Gaussian fits to three-dimensional two-pion correlation functions result in six HBT radii (in contrast to the usual three), all of which depend on the pair emission angle relative to the impact parameter. The order and magnitude of the radius oscillations are quantified by Fourier coefficients, which may be directly related to the spatial tilt and eccentricity of a Gaussian source with no space-momentum correlations (arising, for example, from collective flow). For a more realistic freezeout distribution, the connection between the oscillating radii and the source anisotropy is only approximate. Using a sophisticated transport model to simulate the entire collision evolution and particle decoupling, we have studied the freezeout distribution in coordinate space. The “whole” distribution indeed features a tilted structure and eccentricity, but shows other, less trivial anisotropic structures as well.

The experimentalist, of course, cannot study the distribution directly in coordinate space. We have simulated the experimental situation by constructing two-pion correlation functions for different pair emission angles, fitted each with a Gaussian functional form and extracted Fourier coefficients for each radius. These coefficients were then used in the formalism derived in section II to estimate the tilt and eccentricity. The agreement between these estimates of the anisotropy and the more direct study in coordinate space, was fair. Previous studies [20] of boost-invariant hydrodynamic and blastwave models found that the eccentricity values estimated from two-particle radii were within 30% of the “true” values; this has been used as a systematic error for the eccentricity in experimental studies [10]. Our results using UrQMD are consistent with this 30% value. The present study is the first estimate of the corresponding uncertainty in the tilt, $\theta_s$; the agreement is somewhat worse, on the order of 35%. Given the complications of dynamically-induced homogeneity regions, a time-
evolving emission distribution, non-Gaussianess and “twist” effects, one might easily have expected much worse agreement.

However approximate, quantifying the connection between the radius oscillations and the underlying geometry can be useful. Ideally, the correct model of a heavy ion collision will reproduce all experimental observations; here, this means the HBT radii and their dependence on azimuthal angle. However, when observations are reproduced and others not, connections to the underlying scenario are important. For example, if a model reproduces $R_{\text{long}}$ and $R_{\text{side}}$ but over-estimates $R_{\text{ass}}$ [e.g. 40-42], attention immediately turns to emission duration, which may be associated with the nature of the transition between confined and deconfined states, latent heat, etc. [22, 23, 43].

For the azimuthal dependence of HBT radii, the tilt angle and eccentricities probe different aspects of the dynamics. At AGS energies ($\sim 3.5$ GeV), $\theta_{5}$ reflects the dynamics behind directed flow [25] in the earliest stage of the collision and shows strong dependence of the equation of state used in transport calculations [9]. Meanwhile, the eccentricities represent the geometric and temporal aspects of elliptic flow. It is hoped that the connections we have discussed here, between experimental observations and the underlying source anisotropy, will help future comparative studies focus on the physics most relevant to each observable.

[47] This is discussed further in section 2.8 of [1], where it is called Method II.
[48] In principle, one could correct the correlation functions themselves for the finite $\phi$-binning, and then extract HBT radii from them, as described in [26]. However, especially if the reaction-plane estimation resolution [3] is good (in our model analysis, it
is perfect), it makes no significant difference whether the corre-
lation functions or the radii themselves are corrected for binning
effects [45].
