Abstract. Physalia physalis, also called the Indo-Pacific Portuguese man o’ war or the bluebottle (Physalia utriculus, a synonym), is well known on the east coast of Australia for stinging tens of thousands of beachgoers each year (Daw et al., 2020). The species is found throughout the world’s oceans, in tropical, subtropical and (occasionally) temperate regions (Munro et al., 2019). The bluebottle resembles a jellyfish but is actually a siphonophore, a colonial organism composed of small individual animals called zooids (Totton and Mackie, 1960). There are four zooids depending on each other for survival and performing different functions, such as digestion (gastrozooids), reproduction (gonozooids) and hunting (dactylozooids). The last zooid, the pneumatophore, is a gas-filled float or sac that supports the other zooids and acts like a sail so the bluebottle is constrained to the ocean surface, moving at the mercy of the wind, waves and marine currents. The bluebottle’s long tentacles hang below the float as they drift, fishing for prey to sting and drag up to their digestive zooids (Totton and Mackie, 1960).

For each bluebottle, the float can be oriented towards the left or the right (dimorphism), believed to be an adaptation that prevents the entire population from being washed on shore to die (Totton and Mackie, 1956; Woodcock, 1944). The “left-handed” bluebottles sail to the right of the wind, while the “right-handed” bluebottles sail to the left. The wind will always push the two types of bluebottles in different directions, so at most half the population will be pushed towards the coast (Totton and Mackie, 1956; Woodcock, 1944). The Atlantic Portuguese man o’ war (PMW) is considered the same species as the bluebottle, but with key differences

1 Introduction

Physalia physalis (Fig. 1), also called the Indo-Pacific Portuguese man o’ war or the bluebottle (Physalia utriculus, a synonym), is well known on the east coast of Australia for stinging tens of thousands of beachgoers each year (Daw et al., 2020). The species is found throughout the world’s oceans, in tropical, subtropical and (occasionally) temperate regions (Munro et al., 2019). The bluebottle resembles a jellyfish but is actually a siphonophore, a colonial organism composed of small individual animals called zooids (Totton and Mackie, 1960). There are four zooids depending on each other for survival and performing different functions, such as digestion (gastrozooids), reproduction (gonozooids) and hunting (dactylozooids). The last zooid, the pneumatophore, is a gas-filled float or sac that supports the other zooids and acts like a sail so the bluebottle is constrained to the ocean surface, moving at the mercy of the wind, waves and marine currents. The bluebottle’s long tentacles hang below the float as they drift, fishing for prey to sting and drag up to their digestive zooids (Totton and Mackie, 1960).

For each bluebottle, the float can be oriented towards the left or the right (dimorphism), believed to be an adaptation that prevents the entire population from being washed on shore to die (Totton and Mackie, 1956; Woodcock, 1944). The “left-handed” bluebottles sail to the right of the wind, while the “right-handed” bluebottles sail to the left. The wind will always push the two types of bluebottles in different directions, so at most half the population will be pushed towards the coast (Totton and Mackie, 1956; Woodcock, 1944). The Atlantic Portuguese man o’ war (PMW) is considered the same species as the bluebottle, but with key differences.
in their size and the number of long tentacles used for hunting. The bluebottle’s float rarely exceeds 10 cm and it has one long hunting tentacle that is less than 3 m in length (Fig. 1). In comparison, the PMW has floats of around 15 cm, reported up to 30 cm, and several hunting tentacles that can reach 30 m in mature colonies when fully extended (Munro et al., 2019).

Due to their inability to swim, the movement of the bluebottle can be modelled by calculating the forces acting on it, or by advecting virtual particles in ocean and atmospheric circulation models. Previous studies modelled the movement of the PMW with Lagrangian particle tracking to explain major beaching events. For example, Ferrer and Pastor (2017) were able to estimate the region of origin of a significant beaching event on the Basque coast in August 2010. They ran a Lagrangian model backwards in time, using wind velocity ($V_A$) and a wind drag coefficient ($\lambda = 4.5\%$) as drivers of the PMW motion ($V_{bb} = \lambda V_A$). They found that the region of origin was the North Atlantic subtropical gyre. Prieto et al. (2015) included both the effect of the surface currents ($u$) and wind ($V_{bb} = u + \lambda V_A$) to predict initial colony position of major beaching events in the Mediterranean in 2010. This model assumed the PMW was advected by the surface currents, with the effect of the wind being added with a much higher wind drag coefficient of 10 %. Similarly, Headlam et al. (2020) used beaching and offshore observations to identify a region of origin, using the joint effects of surface currents and wind drag, for the largest mass PMW beaching on the Irish coastline in over 150 years.

These previous models made the key assumption that the PMW’s sailing direction is the same as the wind direction. This may be based on the observation by Totton and Mackie (1960) that in winds stronger than force 4 (i.e. over 8 m s$^{-1}$), the PMW would sail straight downwind with its sail parallel to the wind direction. However, it should be noted that this was a second-hand visual observation of one instance by a single individual. In addition, Totton and Mackie (1960) performed their own experiments and observed that in light winds (about 4 m s$^{-1}$) the PMW balances itself at approximately 40$^\circ$ to the wind (angle of attack), resulting in a completely different course of about 45$^\circ$ relative to the wind. In another experiment, Shannon and Chapman (1983) found that left- and right-handed specimens would separate by about 40$^\circ$ in force 7–8 winds (14–21 m s$^{-1}$). This suggests a course of about 20$^\circ$ relative to the wind rather than both drifting downwind. More recently, Ferrer and González (2020) improved on the model from Ferrer and Pastor (2017) by analysing the same beaching event but incorporating di-morphism and different drift angles relative to the wind direction. They found different regions of origin depending on the drifting angle considered and concluded that the PMWs were likely right-handed.

Iosilevskii and Weihs (2009) took a different approach by expressing the forces acting on the PMW. By considering the equilibrium condition of the aerodynamic (above water) and hydrodynamic (below water) forces, when the velocity of the PMW is constant, they derive equations that can be solved for the PMW’s speed and direction of motion relative to the wind. However, they consider a situation with no background ocean current, where the hydrodynamic force is only the drag, opposed to the PMW course. Here, we expand that model by adding the effect of the ocean current and simplifying the model down to an intuitive generalized vector form which could be implemented in Lagrangian models. We also analyse the impact of key variables such as angle of attack and sail camber (Sect. 4.3).

This paper is structured as follows. First, we explain the methods and key assumptions used for our theoretical model (Sect. 2), followed by the force balance acting on the bluebottle (Sect. 3). We then solve the equilibrium condition (Sect. 4.1), discuss the parameters in the model (Sect. 4.2 and 4.3) and apply the model to a few special cases that were chosen as instructive examples of the bluebottle’s sailing dynamics (Sect. 5). Finally, we compare our results to previous studies and discuss some variables that were not included in the model (Sect. 6).

## 2 Methods

The bluebottle undergoes similar forces to those of a sailboat. Therefore, like Iosilevskii and Weihs (2009), we con-
The forces acting on the bluebottle will be expressed as components on two axes where the force coefficients and affected surface areas are most easily calculated. We call these the $x'$ and $y'$ axes, and they are defined relative to the bluebottle’s sail. The $x'$ axis is along the chord of the sail. The $y'$ axis is perpendicular to the $x'$ axis and goes through the centre of the sail, which is also assumed to be symmetric (Fig. 2). We use the axes labels as subscripts for variables that are related to specific axes. Any vectors in this paper are labelled in bold text and their components are the standard $x$ and $y$ components. Angles that are measured anticlockwise are considered positive, while angles that are measured clockwise are considered negative. The only exception to this is $\beta$, which is always considered positive starting from the $x'$ axis (Fig. 3).

### 3 Forces acting on the bluebottle

We now present the formulas that represent the aerodynamic and hydrodynamic forces acting on the bluebottle. Compared to Iosilevskii and Weihs (2009), we choose not to consider the moment force or the distances between the aerodynamic centre of effort and the hydrodynamic centre of effort, as these variables would require very rough estimates. Furthermore, Iosilevskii and Weihs (2009) do not use these variables in the final equations that describe the course and speed but rather use them to analyse the PMW's sail contraction and tilting of their tentacles – which we do not consider here. The moment force would result in a torque, and thus the orientation of the bluebottle would be influenced by a combination of the wind and current conditions. However, similarly to the leeway methodology (discussed further in Sect. 6), the orientation behaviour of the bluebottle (mainly represented by the angle of attack) can instead be determined by observations made in physical experiments.

#### 3.1 Aerodynamic force

The aerodynamic force on the bluebottle $F_A$ is expressed as components on the $x'$ and $y'$ axes. This can be represented by the standard aerodynamic force equation, often used for lift and drag force on an aeroplane wing, for instance.

\[
\begin{aligned}
F_{Ax'} &= \frac{1}{2} \rho_A S_x V_A^2 C_{Ax'}, \\
F_{Ay'} &= \frac{1}{2} \rho_A S_y V_A^2 C_{Ay'},
\end{aligned}
\]  

where $\rho_A$ is the density of the air (taken as 1.225 kg m$^{-3}$), $S'_x$ and $S'_y$ are the areas of the sail perpendicular to the respective axis, $C_{Ax'}$ and $C_{Ay'}$ are the respective force coefficients, and $V_A$ is the wind speed. Wind speed is used rather than relative wind speed because the speed of the bluebottle is at least 1 order of magnitude smaller compared to the wind speed.
The areas $S_x'$ and $S_y'$ are fixed values for a particular bluebottle. On the other hand, the force coefficients $C_{Ax'}$ and $C_{Ay'}$ are functions of the angle of attack $\beta$. Note that here we separately calculate the components of the aerodynamic force on two different axes. This is because the values of the $x'$ and $y'$ force coefficients and areas will vary significantly.

Considering the order of magnitude of the parameters (discussed in Sect. 4.2), for wind speeds from 1 to 10 m s$^{-1}$, $F_{Ax'}$ will range from $7 \times 10^{-6}$ to $7 \times 10^{-4}$ N, and $F_{Ay'}$ will range from $1 \times 10^{-4}$ to $1 \times 10^{-2}$ N.

### 3.2 Hydrodynamic force

The hydrodynamic force on the bluebottle $F_H$ is dependent on the relative current, which is the current felt by the bluebottle as it is in motion. The magnitude of the hydrodynamic force can be represented by an equation of the same form as the aerodynamic force.

$$ F_H = \frac{1}{2} \rho_H S_H V_{RH}^2 C_H, \quad (2) $$

where $\rho_H$ is the density of the water (taken as 1025 kg m$^{-3}$), $S_H$ is the projected area of the submerged bluebottle surface onto the bluebottle’s plane of symmetry, $C_H$ is the force coefficient, and $V_{RH}$ is the speed of the current relative to the bluebottle (Fig. 3). Considering the order of magnitude of the parameters, $F_H$ will range from $1 \times 10^{-4}$ to $1 \times 10^{-2}$ N.

The hydrodynamic force $F_H$ is calculated using a single equation, thus using just one value for both the area and the force coefficient. Unlike the aerodynamic force, we do not need to calculate two components of the force separately. This is because the submerged body of the bluebottle is close to cylindrical, so there is not much variance in the value of the area or force coefficient. The relative speed of the current can be represented by

$$ V_{RH} = \sqrt{V_{RHx}^2 + V_{RHy}^2}, \quad (3) $$

with

$$ \begin{align*}
V_{RHx} &= u - V_{bbx}, \\
V_{RHy} &= v - V_{bbv},
\end{align*} \quad (4) $$

where $V_{RHx}$ and $V_{RHy}$ are the components of the relative velocity of the current in the respective axes, $u$ and $v$ are the $x$ and $y$ components of the ocean current velocity, and $V_{bbx}$ and $V_{bbv}$ are the $x$ and $y$ components of the bluebottle velocity vector.

To later solve for the equilibrium condition (Sect. 4.1), when the velocity of the bluebottle is constant; hence, there is no acceleration since the bluebottle does not swim. Based on Newton’s Second Law of Motion, this occurs when the net forces acting on the bluebottle are zero. Hence, the aerodynamic and hydrodynamic forces must be equal in magnitude on each axis. Expressing the equilibrium conditions,

$$ \begin{align*}
F_{Ax'} &= F_{Hx'}, \\
F_{Ay'} &= F_{Hy'},
\end{align*} \quad (6) $$

along the $x'$ and $y'$ axes yields the following equations:

$$ \begin{align*}
\rho_A S_{x'} V_{A}^2 C_{Ax'} &= \rho_H S_H V_{RHx}^2 C_H \cos \beta, \\
\rho_A S_{y'} V_{A}^2 C_{Ay'} &= \rho_H S_H V_{RHy}^2 C_H \sin \beta. 
\end{align*} \quad (7) $$

Dividing the equations in Eq. (7) gives

$$ \frac{S_{x'} C_{Ay'}}{S_{y'} C_{Ax'}} = \tan \beta, \quad (8) $$

while taking the sum of squares of the equations in Eq. (7), then simplifying and taking the root gives

$$ V_{RH} = \lambda V_A, \quad (9) $$

where

$$ \lambda = \sqrt{\frac{\rho_A \sqrt{(S_{x'} C_{Ax'})^2 + (S_{y'} C_{Ay'})^2}}{\rho_H S_H C_H}}. $$
This equation gives an expression for the coefficient $\lambda$ (shape parameter), where previous studies have used constant values. We see that $\lambda$ is based on the ratio of densities, bluebottle areas and force coefficients. Note that $\lambda$ is also dependent on the angle of attack $\beta_a$, since this affects the value of the force coefficients.

Once $\beta$ and $V_{RH}$ are known from Eqs. (8) and (9), we calculate the velocity and course of the bluebottle in terms of the $x$ and $y$ components. The $x$ and $y$ components of $V_{RH}$, the relative velocity of the current, are

$$
\begin{align*}
V_{RHx} &= V_{RH} \cos \alpha \\
V_{RHY} &= V_{RH} \sin \alpha,
\end{align*}
$$

(10)

where $\alpha$ is the angle between the $x$ axis and the relative current vector. Relating $\alpha$ to known angles (Fig. 2) gives

$$
\begin{align*}
\alpha &= \beta - \beta_a + \beta_w, \text{ for a left-handed bluebottle (Fig. 8)} \\
\alpha &= -\beta - \beta_a + \beta_w, \text{ for a right-handed bluebottle (Fig. A1)},
\end{align*}
$$

(11) \quad (12)

where $\beta_w$ is the angle of the wind (between the $x$ axis and the wind), and $\beta_a$ is the angle of attack (between the $x'$ axis and the wind, Fig. 2) and $\beta$ is the angle between the $x'$ axis and the relative velocity of the current (Fig. 3). Note that $\beta$ is always considered positive. To find $\alpha$, we choose a constant value for $\beta_a$ (see Sect. 5 and Fig. 8). The absolute direction of the wind $\beta_w$ should also be known.

Once $\alpha$ is known, we find the velocity of the bluebottle relative to the $x$ and $y$ axes using Eqs. (4) and (10):

$$
\begin{align*}
V_{bbx} &= u - V_{RH} \cos \alpha \\
V_{bbx} &= v - V_{RH} \sin \alpha.
\end{align*}
$$

(13)

Finally, using Eq. (9),

$$
\begin{align*}
V_{bbx} &= u - \lambda V_A \cos \alpha \\
V_{bbx} &= v - \lambda V_A \sin \alpha.
\end{align*}
$$

(14)

Here, we can see the bluebottle velocity is a linear combination of the current velocity and wind velocity with some scaling and rotation. However, the velocity is non-linear with respect to the angle of attack, since both $\alpha$ and $\lambda$ are dependent on $\beta_a$.

This solution for the bluebottle’s velocity can be expressed in a generalized vector form. For a left-handed bluebottle, we have

$$
\begin{align*}
V_{bb} &= u - \lambda V_A \left( \begin{array}{c} \cos \alpha \\ \sin \alpha \end{array} \right), \text{ with } u = \left( \begin{array}{c} u \\ v \end{array} \right) \\
&= u - \lambda V_A \left( \begin{array}{c} \cos(\beta - \beta_a + \beta_w) \\ \sin(\beta - \beta_a + \beta_w) \end{array} \right) \\
&= u - \lambda V_A \left( \begin{array}{c} \cos(\beta - \beta_a) \cos \beta_w - \sin(\beta - \beta_a) \sin \beta_w \\ \sin(\beta - \beta_a) \cos \beta_w + \cos(\beta - \beta_a) \sin \beta_w \end{array} \right).
\end{align*}
$$

Now using the $x$ and $y$ components of the wind velocity, $V_{Ax} = V_A \cos \beta_w$ and $V_{Ay} = V_A \sin \beta_w$, we have

$$
\begin{align*}
V_{bb} &= u - \lambda V_{Ax} \left( \begin{array}{c} \cos(\beta - \beta_a) \\ \sin(\beta - \beta_a) \end{array} \right) - \lambda V_A \left( \begin{array}{c} \sin(\beta - \beta_a) \\ \cos(\beta - \beta_a) \end{array} \right) \\
&= u - \lambda \left( \begin{array}{c} \cos(\beta - \beta_a) - \sin(\beta - \beta_a) \\ \sin(\beta - \beta_a) \cos(\beta - \beta_a) \end{array} \right) \left( \begin{array}{c} V_{Ax} \\ V_{Ay} \end{array} \right) \\
&= u - \lambda \left( \begin{array}{c} \cos(\beta - \beta_a) - \sin(\beta - \beta_a) \\ \sin(\beta - \beta_a) \cos(\beta - \beta_a) \end{array} \right) V_A.
\end{align*}
$$

Using the trigonometric identities $\cos \theta = -\cos(180^\circ - \theta)$ and $\sin \theta = \sin(180^\circ - \theta)$, we have

$$
\begin{align*}
V_{bb} &= u + \lambda \left( \begin{array}{c} \cos(180^\circ - \beta + \beta_a) \\ -\sin(180^\circ - \beta + \beta_a) \end{array} \right) \left( \begin{array}{c} V_{Ax} \\ V_{Ay} \end{array} \right) V_A,
\end{align*}
$$

(15)

and finally

$$
\begin{align*}
V_{bb} &= u + \lambda \mathbf{R}(180^\circ - \beta + \beta_a)V_A,
\end{align*}
$$

(16)

These results show that the velocity of the bluebottle is a linear combination of the ocean current velocity vector $\mathbf{u}$ and the wind velocity vector scaled by the shape parameter $\lambda$ and multiplied by a clockwise rotation matrix of $180^\circ - \beta + \beta_a$. This can be interpreted as the bluebottle simply drifting with the current, while the force imparted by the wind on the sail is a proportion ($\lambda$) of the wind velocity at an angle of $180^\circ - \beta + \beta_a$ clockwise from the wind direction.

We refer to Eqs. (15) and (16) as a generalized vector form. By adding assumptions, we can simplify our form to match Lagrangian models seen in previous literature. Hence, we can explain the assumptions required to use these previous models. This vector form is the link between the practical papers that used simple vector models (Ferrer and Pastor, 2017; Ferrer and González, 2020; Prieto et al., 2015) and the theoretical bottom-up approach used by Iosilevskii and Weis (2009).

### 4.2 Determining parameters

The formulation shown in Eqs. (15) and (16) for the velocity of the bluebottle depends on several parameters. Firstly,
we will consider the parameters required to find the shape parameter \( \lambda \) (see Eq. 9).

The areas required were measured from photographs taken at Coogee Beach, Sydney, on 23 January 2019. \( S_y' \) (area of the bluebottle’s sail on the \( y' \) axis) was measured by estimating the area as a segment of a circle. This gave a value of \( 3\pi - \frac{9\sqrt{3}}{4} \text{ cm}^2 \) (approximately 5.5 cm\(^2\)). \( S_x' \) (area of the bluebottle’s sail on the \( x' \) axis) was measured by estimating the area as a triangle. This gave a value of 1.12 cm\(^2\).

We assume the submerged body of the bluebottle is a cylinder, so \( S_H \) will be the rectangular cross section made by cutting through the cylinder’s diameter. This is measured as 3.78 cm\(^2\). Note that the tentacles are not taken into account since they can retract or vary their angle. \( C_H \) can be estimated as the drag coefficient of a cylinder, which is dependent on Reynolds number. The Reynolds number (for seawater) is defined as

\[
Re = \frac{\rho u L}{\mu},
\]

where \( u \) is the current speed with respect to the bluebottle (order of 0.1–1 m s\(^{-1}\)), \( L \) is the characteristic length dimension (simply the diameter for a cylinder, which is 0.027 m), and \( \mu \) is the dynamic viscosity of seawater (order of 10\(^{-3}\) Pa s, dependent on temperature). This gives a Reynolds number between 2781 and 27810 (turbulent flow). For these values, the drag coefficient of a cylinder is very close to 1, so we estimate \( C_H \) as 1.

The force coefficients \( C_{Ax'} \) and \( C_{Ay'} \) depend on the orientation of the bluebottle relative to the wind, which is measured by the angle of attack \( \beta_a \). \( C_{Ax'} \) does not need to be estimated accurately because its value has little effect on the bluebottle’s course and speed, since the product \( S_y' C_{Ax'} \) (used in Eqs. 8 and 9) is \( O(10^{-2}) \) while \( S_y' C_{Ay'} \) is \( O(10^{-4}) \). Hence, for \( C_{Ax'} \), we use the same constant value as Iosilevskii and Weihs (2009), which is 0.1.

Iosilevskii and Weihs (2009) derive the following expression for the force coefficient \( C_{Ay'} \) as a function of angle of attack by considering the aerodynamic forces acting on a wing surface (slender sail theory).

\[
C_{Ay'} = \frac{\pi A}{2} \beta_a + \frac{4\pi A f_0}{3 c} \quad \text{(18)}
\]

\[
A = \frac{b^2}{S_y'},
\]

where \( A \) is the aspect ratio of the sail (calculated using \( b \), the sail height, and \( S_y' \), the sail area), \( \beta_a \) is the angle of attack (see Fig. 2), \( f_0 \) is the sail camber, and \( c \) is the sail chord (Fig. 4). \( f_0/c \) is referred to as the camber ratio.

Using our bluebottle measurements, we have an aspect ratio of roughly 0.35 (half the value used by Iosilevskii and Weihs (2009), whose estimates were based on the PMW) and a sail chord of 5.2 cm.

It should be noted that in aerodynamic theory (for example, Abbott et al., 1945), it has been found that the lift coefficient of an airfoil increases roughly linearly with angle of attack until the lift coefficient approaches a maximum. This expression does not take this maximum into account.

### 4.3 Influence of angle of attack on bluebottle course

In this section, we discuss two key parameters: the angle of attack and the sail camber. These are related to the aerodynamic force, so we will assume there is no current and examine how changing the angle of attack varies the bluebottle’s course relative to the wind. Firstly, a change in the angle of attack means the orientation of the bluebottle relative to the wind is changing. This results in a different course relative to the wind. Secondly, the force coefficient \( C_{Ay'} \) changes based on the angle of attack, which also varies the bluebottle’s course (Eq. 8).

From the parameterization of \( C_{Ay'} \) (Eq. 18), the effect of the angle of attack on the bluebottle’s course is dependent on the camber of the sail. Figure 5 illustrates such a link, showing that the camber is only relevant at low angles of attack (0 to 10\(^{\circ}\)). At higher angles of attack the relationship between angle of attack and the bluebottle course relative to the wind becomes linear. This is because \( C_{Ay'} \) has become sufficiently large and hence the change in \( C_{Ay'} \) is insignificant. At this point, a 10\(^{\circ}\) change in the bluebottle’s orientation simply results in a 10\(^{\circ}\) change in the bluebottle’s course. As the camber becomes large, \( C_{Ay'} \) becomes sufficiently large even at zero angle of attack, and the relationship tends towards linearity.

Previous modelling studies assumed a course straight downwind, which corresponds to a bluebottle course of 0\(^{\circ}\) relative to the wind. This behaviour has been described by Totton and Mackie (1960), who reported that in winds...
is parallel to the wind direction and perpendicular to its sail. However, to our knowledge, this situation has not been reported from observations, and it seems unlikely that the bluebottle balances itself perpendicular to the wind.

5 Special cases

5.1 Model and assumptions for downwind drift

We now discuss the assumptions required to reduce our generalized vector form to simpler models seen in some previous studies. Firstly, we must assume the bluebottle drifts straight downwind with its sail parallel to the wind direction under all conditions, despite the observation by Totton and Mackie (1960) that the PMW sails in this manner only in winds stronger than force 4 (i.e. over 8 m s\(^{-1}\)). Considering a downwind drift, the sail orientation corresponds to an angle of attack \(\beta_a\) of 0\(^\circ\) (Fig. 6). Substituting this into our vector form (Eq. 15) gives

\[
V_{bb} = u + \lambda R (180^\circ - \beta) V_A.
\]

Now, the bluebottle will only sail straight downwind if the force coefficient \(C_{A'y}'\) equals zero, resulting in no aerodynamic force perpendicular to the sail (Fig. 7). At an angle of attack of 0\(^\circ\), we expect \(C_{A'y}'\) to equal zero only if there is no camber (Fig. 6a). Hence we must also make this assumption that the sail camber is zero. Based on Eq. (8) and the fact that the relative current will always be opposite the wind (in order to have an equilibrium condition), we have \(\beta = 180^\circ\) (Fig. 7), and \(R\) is the identity matrix. Using Eq. (16) also gives this result. This gives a form that we have seen in previous literature (discussed in Sect. 6):

\[
V_{bb} = u + \lambda V_A. \quad (19)
\]

We can also exclude the current by assuming \(u = 0\) to reach another form seen in previous literature:

\[
V_{bb} = \lambda V_A. \quad (20)
\]

Hence, we see that the models used in previous literature can be verified by our generalized form but require fairly strong assumptions of zero angle of attack in all conditions and no camber. In Sect. 5.2 and 5.3, we lift these assumptions to further explore the drifting dynamics of the bluebottle.

5.2 Case with angle of attack of 40\(^\circ\) and no current

Totton and Mackie (1960) observed that in light winds the PMW balances itself at approximately 40\(^\circ\) to the wind. Hence, we now assume \(\beta_a\) has a value of 40 or \(-40^\circ\), depending on whether the bluebottle is right-handed (left-sailing) or left-handed (right-sailing), respectively. Since the orientation of the bluebottle is constant relative to the wind, the sail is always hit by the wind at the same angle and the force coefficients \(C_{Ax}'\) and \(C_{A'y}'\) can be considered as constants. For
Figure 7. Case with no current for a left-handed (right-sailing) bluebottle sailing straight downwind with sail parallel to the wind direction ($\beta_a = 0^\circ$). Note that the wind direction and bluebottle course are on the $x'$ axis. A right-handed (left-sailing) bluebottle would have the exact same course in this case.

Figure 8. Case with no current for a left-handed (right-sailing) bluebottle ($\beta_a = -40^\circ$). Note that $\beta_a$ is negative because it is the angle between the $x'$ axis and the wind, which is clockwise. The lengths of course and $V_{RH}$ are to scale. Wind vector length has been scaled down by a factor of 8.

Figure 9. Case with current running southeast for a left-handed (right-sailing) bluebottle ($\beta_a = -40^\circ$). Diagram in the bottom right shows the vector addition between the bluebottle's course, the current and the relative current felt by the bluebottle. The lengths of the course, current and $V_{RH}$ are to scale, based on a current speed that is 5% of the wind speed. Wind vector length has been scaled down by a factor of 8.

Unlike Sect. 5.2, considering the effect of background ocean current means that the relative current velocity $V_{RH}$ is no longer directly opposite the bluebottle’s course (Fig. 9). However, since the wind conditions and other variables have not changed from Sect. 5.2, the aerodynamic force is identical. Hence, we also require the relative current vector to be identical since this determines the hydrodynamic force, which must balance out the aerodynamic force in order to have an equilibrium condition. This means that the course of the bluebottle must adjust such that $V_{RH}$ is in the same position as Sect. 5.2 ($\beta = 87.1^\circ$). Figure 10 shows examples of different current conditions with a constant wind. In each example, $V_{RH}$ is kept in the same position by adjusting the bluebottle’s course.
Figure 10. Examples of different ocean current directions for a constant wind. Top row depicts left-handed (right-sailing) bluebottles. Bottom row depicts right-handed (left-sailing) bluebottles for the same wind and current conditions. Grey vectors indicate confidence intervals for the bluebottle course if we consider that the angle of attack ($\beta_a$) could be 30 to 50°. Note that for each form, $\mathbf{V}_{RH}$ must always point in the same direction. The lengths of the course, current and $\mathbf{V}_{RH}$ are to scale, based on a current speed that is 5% of the wind speed. Wind vector length has been scaled down by a factor of 8.

6 Discussion and conclusion

We have added the ocean background current to an existing theoretical model of aerodynamic and hydrodynamic forces acting on a bluebottle. We then solve for an equilibrium condition to create a generalized vector model for the speed and course of the bluebottle. Adding assumptions to our generalized model results in simplification to models that have been seen in previous literature. The generalized vector form is the link between the practical papers that used simple Lagrangian vector models and the theoretical papers that used a bottom-up approach. We also identify and discuss the key parameters: shape ($\lambda$), angle of attack and camber. Finally, we find that under typical sailing conditions reported in the literature (angle of attack of 40°), the bluebottle will drift at an angle of 52.9° from the wind at 2.66% of the wind speed, plus the velocity of the ocean background current.

It is worth noting that the form of Eqs. (15) and (16) is different from leeway methods, which consider the motion of the object as a wind vector plus leeway (divergence from the wind). The leeway is often estimated using physical experiments and statistics. This methodology has been used in many previous studies (Breivik et al., 2011; Hackett et al., 2006; Ni et al., 2010; Wang et al., 2015). Our theoretical bottom-up approach to calculate bluebottle drift using force balance in equilibrium is a completely different methodology, despite the similar-looking vector form that results from both techniques.

Our results compare well with previous Lagrangian model parameterizations. Ferrer and Pastor (2017) modelled the drift velocity of PMWs as wind velocity multiplied by a wind drag coefficient estimated from numerical simulations. The current was not used because wind was considered to be the main mechanism, based on Ferrer et al. (2014), who used symmetric fish tags for model calibration. The model calibration used in Ferrer et al. (2014) included a calculation of surface current as the combination of ROMS (Regional Ocean Modelling System) current and wind. They also assumed that the PMWs drift straight downwind. This matches our form in Eq. (20), where we assume the bluebottle has zero angle of attack and there is no current. The model used by Prieto et al. (2015) was advection by surface currents (computed by ROMS model) plus 10% of wind velocity. This matches our form in Eq. (19), still assuming an angle of attack of 0°.

In comparison, we have a generalized form for calculating the drift of a bluebottle for different angles of attack. We use a bottom-up approach for our wind velocity coefficient $\lambda$, which is determined by the specific areas and force coefficients of the bluebottle. We find that when the bluebottle has an angle of attack of 40°, as suggested by observations, $\lambda = 0.0266$, and the wind pushes the bluebottle on a course of about 53° to the wind. This value of $\lambda$ falls within the range of 0.02–0.045 which was tested by Ferrer and Pastor (2017) but differs from the 10% used by Prieto et al. (2015). The wind drift angle of 53° is similar to the 45° observed by Totton and Mackie (1960) and used amongst others in the model of Ferrer and González (2020). The $\alpha$ term in our model accounts for the angle of the current, the angle of the wind and the bluebottle’s angle of attack. Our model also incorporates the current, which has a significant effect even at 10 m s$^{-1}$ winds. Indeed, at wind speeds of O(10), the speed imparted onto the bluebottle from the wind is about
0.266 m s\(^{-1}\) (2.66\% of wind speed), which is the same order of magnitude as the speed of ocean currents. Hence based on our vector form, the current should not be ignored when predicting the drift of the bluebottle. Note that the current relevant for this study is the surface ocean current which would be felt by the bluebottle. Relatively good results from modelling studies which did not take into account that the ocean current can be explained by the great impact the wind has on the top few centimetres of the ocean.

It should be noted that the influence of waves is not taken into account in our model. The impact force of waves has an effect on drifters (Szelangiewicz and Zelazny, 2018), but several additional variables and functions are required to calculate this impact force. This will make our model significantly more complex and currently cannot realistically be added. The effect of Stokes drift, however, could be added into the ocean surface current vector, following Clarke and Vander (2018), for instance. Stokes drift is a phenomenon that occurs on the ocean surface where the surface waves affect the net particle movement in the top 1 or 2 m of the ocean, in the direction of the waves. Clarke and Vander (2018) found that Stokes drift is mostly in the direction of the wind, and thus it is mainly due to shorter waves generated by the local wind. It was also found that the magnitude of Stokes drift can be approximated by

\[
u_{\text{Stokes}} = 4.4u_* \ln \left( \frac{0.0074u_{10}}{u_*} \right),
\]

where \(u_{10}\) is the 10 m wind speed and \(u_*\) is a parameter calculated by

\[
u_* = \sqrt{|\tau_0| / \rho_w},
\]

where \(|\tau_0|\) is the wind stress magnitude and \(\rho_w\) is the density of water. Assuming a constant drag coefficient, Clarke and Vander (2018) then show that \(\nu_{\text{Stokes}}\) can be estimated as 1\% of \(u_{10}\). This Stokes drift estimate can be added as an additional term to Eq. (15), giving

\[
V_{bb} = u + 0.01V_A + \lambda R (180^\circ - \beta + \beta_a) V_A.
\]

However, another consideration is that large waves (at high wind speeds) may break on top of the bluebottle and result in the bluebottle becoming imbalanced or even toppling over. Our model cannot predict the behaviour of the bluebottle in this situation.

An assumption we used in Sect. 5 was a constant value for the angle of attack. In reality, the orientation of the bluebottle would be influenced by a combination of the wind and current conditions. In particular, observations suggest that the angle of attack decreases from about 40 to 0\(^\circ\) as wind speed increases (Totton and Mackie, 1960). More information from lab experiments and in situ surveys in the future is required to determine the value of this key parameter and its variability. Instead of using a constant value for the angle of attack, it could be implemented in the model as a function of wind speed, for example.

Another assumption in the model is that the body of the bluebottle is assumed to be a perfectly symmetrical cylinder with no tentacles. In reality, the submerged body is not perfectly symmetrical so the hydrodynamic force would also influence the orientation of the bluebottle’s sail and body to some extent, like the keel of a sailboat. However, since the bluebottle can extend and retract the tentacle, changing its length and angle, it is hard to model. The drag force from the bluebottle’s single tentacle (calculated using equations from Iosilevskii and Weihs (2009)) is \(O(10^{-4})\), which is insignificant compared to the overall hydrodynamic force of \(O(10^{-2})\) acting on the bluebottle.

This study is focused on the bluebottles found on the east coast of Australia. Different parameter values may be required for the larger PMW. For example, Iosilevskii and Weihs (2009) use an estimate of 0.7 for the aspect ratio of the PMW’s sail, which affects the force coefficient \(C_{\lambda y'}\) (Sect. 4.2). This is much larger than our measured aspect ratio of 0.35 for the bluebottle’s sail. In Sect. 5.2, we conclude that at an angle of attack of 40\(^\circ\) and no current, a left-handed bluebottle will drift at an angle of 52.9\(^\circ\) clockwise from the wind at 2.66\% of the wind speed. A PMW in the same conditions will drift at an angle of 51.5\(^\circ\) clockwise from the wind at 3.73\% of the wind speed. While the drift angle is almost the same, the velocity of the PMW is 40\% higher than the bluebottle due to the higher aspect ratio leading to a larger force coefficient \(C_{\lambda y'}\). It is worth noting that the drag caused by the PMW’s many long tentacles may affect its velocity significantly more than for the bluebottle.

Further research that would supplement this study include

- physical experiments to observe bluebottle drifting and estimate the key parameter values (e.g. force coefficients, angle of attack, camber) of our model; and
- a detailed understanding of the specific habitat and life cycle of the bluebottle to determine the starting point for a drift model.

We hope our work, creating a generalized model for bluebottle drift, encourages new research in this area and helps in the development of accurate numerical tracking and, ultimately, a forecasting tool that can prevent tens of thousands of beachgoers from experiencing painful bluebottle stings.
Appendix A

Figure A1. Case with no current for a right-handed (left-sailing) bluebottle ($\beta_a = 40^\circ$). The lengths of course and $V_{RH}$ are to scale. Wind vector length has been scaled down by a factor of 8.

Data availability. No data sets were used in this article.

Author contributions. DL led the writing of the manuscript, completed the derivations and performed the calculations, under the supervision of AS and SG. AS contributed to writing the manuscript and the derivations. SG provided the idea and helped with derivation and writing of the manuscript.
