ABSTRACT
The stellar initial mass function (IMF) is believed to be non-universal among early-type galaxies (ETGs). Parameterizing the IMF with the so-called IMF mismatch parameter $\alpha_{\text{IMF}}$, which is a measure of the stellar mass-to-light ratio of an ensemble of stars and thus of the ‘heaviness’ of its IMF, one finds that for ETGs $\alpha_e$ (i.e. $\alpha_{\text{IMF}}$ integrated within the effective radius $R_e$) increases with $\sigma_e$ (the line-of-sight velocity dispersion $\sigma_{\text{los}}$ integrated within $R_e$) and that, within the same ETG, $\alpha_{\text{IMF}}$ tends to decrease outwards. We study the effect of dissipationless (dry) mergers on the distribution of the IMF mismatch parameter $\alpha_{\text{IMF}}$ in ETGs using the results of binary major and minor merging simulations. We find that dry mergers tend to make the $\alpha_{\text{IMF}}$ profiles of ETGs shallower, but do not alter significantly the shape of the distributions in the spatially resolved $\sigma_{\text{los}}$ space. Individual galaxies undergoing dry mergers tend to decrease their $\alpha_e$ due to erosion of $\alpha_{\text{IMF}}$ gradients and mixing with stellar populations with lighter IMF. Their $\alpha_e$ can either decrease or increase, depending on the merging orbital parameters and mass ratio, but tends to decrease for cosmologically motivated merging histories. The $\alpha_e - \sigma_e$ relation can vary with redshift as a consequence of the evolution of individual ETGs: based on a simple dry-merging model, ETGs of given $\sigma_e$ are expected to have higher $\alpha_e$ at higher redshift, unless the accreted satellites are so diffuse that they contribute negligibly to the inner stellar distribution of the merger remnant.

Key words: galaxies: elliptical and lenticular, cD – galaxies: evolution – galaxies: formation – galaxies: interactions – galaxies: kinematics and dynamics – stars: luminosity function, mass function

1 INTRODUCTION
There is growing evidence that the stellar initial mass function (IMF) is not universal. Not only do different galaxies have different stellar IMFs, but, at least in some cases, there are indications that the IMF is also different in different regions of the same galaxy (see e.g. Hopkins 2018; Smith 2020). When the single stars are not resolved in observations, we have access only to indirect information about the stellar IMF, such as, for instance, the so called IMF mismatch parameter\textsuperscript{1}

\begin{equation}
\alpha_{\text{IMF}} \equiv \frac{(M_*/L)_{\text{true}}}{(M_*/L)_{\text{ref}}}, \quad (1)
\end{equation}

where $(M_*/L)_{\text{true}}$ is the true stellar mass-to-light ratio of an ensemble of stars (in a given band) and $(M_*/L)_{\text{ref}}$ is the stellar mass-to-light ratio (in the same band) that one would infer assuming a reference IMF, for instance the Salpeter (1955), the Kroupa (2001) or the Chabrier (2003) IMF (Treu et al. 2010). $\alpha_{\text{IMF}}$ is a quantity integrated over the stellar population, which, per se, does not contain information on the shape of the IMF. Broadly speaking, IMFs with high $\alpha_{\text{IMF}}$ are said to be ‘heavy’: a high value of $\alpha_{\text{IMF}}$ can be due to an overabundance of low-mass stars (bottom-heavy IMF), but also of high-mass stars (top-heavy IMF; Bastian et al. 2010).

When large samples of massive early-type galaxies (ETGs) are considered, an empirical correlation is found between the IMF and the central stellar velocity dispersion, in the sense that ETGs with higher velocity dispersion have, on average, heavier IMF (Treu et al. 2010; Cappellari et al. 2012; Conroy & van Dokkum 2012; Dutton et al. 2012; Tortora et al. 2013; Spiniello et al. 2014; Li et al. 2017; Rosani et al. 2018). For instance, for a sample of

\textsuperscript{1} E-mail: carlo.nipoti@unibo.it
\textsuperscript{1} In the literature the IMF mismatch parameter $\alpha_{\text{IMF}}$ is sometimes referred to as effective IMF, mass excess or excess stellar mass-to-light ratio.
present-day ETGs with $90 \text{ km s}^{-1} \leq \sigma_e \leq 270 \text{ km s}^{-1}$, taking as reference IMF the Salpeter IMF, Posacki et al. (2015) find
\[
\log \alpha_e = (0.38 \pm 0.04) \log \left( \frac{\sigma_e}{200 \text{ km s}^{-1}} \right) + (-0.06 \pm 0.01),
\]
with intrinsic scatter 0.12 dex in $\alpha_e$ at given $\sigma_e$, where the effective IMF mismatch parameter $\alpha_e$ is the IMF mismatch parameter measured within the effective radius $R_e$ and the effective velocity dispersion $\sigma_e$ is the central stellar velocity dispersion measured within $R_e$. It must be stressed that some individual galaxies are found to deviate substantially from this relation: in particular, there are cases of massive (high-$\sigma_e$) ETGs with light IMF (Smith et al. 2015; Collier et al. 2018; Sonnenfeld et al. 2019).

Spatially resolved estimates of $\alpha_{IMF}$ in ETGs have revealed the presence of IMF gradients: $\alpha_{IMF}$ is higher in the centre than in the outer regions of individual galaxies, ranging from an IMF heavier than the Salpeter IMF to a lighter IMF with Chabrier-like IMF (Martín-Navarro et al. 2015a; Davis & Mcdermid 2017; van Dokkum et al. 2017; Zielensiewski et al. 2017; Oldham & Auger 2018; Sonnenfeld et al. 2018; La Barbera et al. 2019; but see also Alton et al. 2017, 2018 and Vaughan et al. 2018, who find no significant IMF radial gradients in their samples of ETGs).

In the currently favoured hierarchical model of galaxy formation, ETGs are believed to form in two phases (Oser et al. 2010): a first mostly dissipative phase of in-situ star formation at $z \geq 2$ and a second phase of accretion of stars mainly via dissipationless (`dry') mergers at $z \leq 2$ (see also section 10.8 of Cimatti, Fraternali & Nipoti 2019). In this context, the correlation between $\alpha_e$ and $\sigma_e$ observed for present-day massive ETGs must be produced by the combination of the above two phases. Focusing on the second phase, Sonnenfeld, Nipoti & Treu (2017) studied the redshift evolution of the $\alpha_e$-$\sigma_e$ relation since $z \approx 2$, considering cosmologically motivated merging hierarchies in the simple case in which all the mergers are dissipationless and the stellar populations mix completely in the mergers. Sonnenfeld et al. (2017) found that, as a consequence of the accretion of lower-mass satellites, both $\alpha_e$ and $\sigma_e$ of massive ETGs decrease with cosmic time. Nevertheless, in this model the $\alpha_e$-$\sigma_e$ relation remains essentially unaltered as cosmic time goes on, because individual massive ETGs move in the $\sigma_e$-$\alpha_e$ plane roughly along the $\alpha_e$-$\sigma_e$ relation.

The model of Sonnenfeld et al. (2017) is based on a few simplifying assumptions, which are only partially justified: the stellar velocity dispersion is assumed to be proportional to the host halo virial velocity dispersion, neither dissipation nor star formation is allowed during the merger, and any gradient in the $\alpha_{IMF}$ distribution within galaxies is neglected. Blancato, Genel & Bryan (2017) studied the same process with a more realistic, though not fully self-consistent approach, performing a post-processing analysis of the Illustris cosmological hydrodynamic simulation (Vogelsberger et al. 2014). Blancato et al. (2017) found that, at the time of star formation, $\alpha_{IMF}$ must vary strongly with the local velocity dispersion in order to reproduce the observed $\alpha_e$-$\sigma_e$ relation of present-day ETGs. More recently Barber et al. (2018, 2019a,b) revisited the problem of the theoretical origin and evolution of the $\alpha_e$-$\sigma_e$ relation of ETGs in a more self-consistent way by performing cosmological hydrodynamic simulations in which, when stars form, the IMF depends on the local pressure of the gas. The models considered by Barber et al. are calibrated to reproduce the observed present-day trend of $\alpha_e$ increasing with $\sigma_e$, assume that in higher-pressure environments the stars form with heavier IMF, either bottom-heavy (model ‘LoM’) or top-heavy (model ‘HiM’). Barber et al. (2019b) find that, at given $\sigma_e$, the average $\alpha_e$ of ETGs tends to be higher at higher $z$ for model ‘LoM’, in which $\alpha_{IMF}$ is essentially independent of the age of the stellar population, and lower at higher $z$ for model ‘HiM’, in which instead $\alpha_{IMF}$ is significantly lower for younger stellar populations. The question of the non-universality of the IMF in the context of galaxy formation and evolution has been explored also with semi-analytical models in various papers (Nagashima et al. 2005; Calura & Menci 2009; Chattopadhyay et al. 2015; Gargiulo et al. 2015; Fontanot et al. 2017), which however focus on the evolution of the chemical properties of galaxies without exploring specifically ongoing correlations of the IMF with the stellar velocity dispersion.

In this paper, we approach theoretically the question of the evolution of the $\alpha_{IMF}$ of ETGs by taking into account in detail $\alpha_{IMF}$ gradients within galaxies. In a cosmological context, the $\alpha_{IMF}$ gradients of simulated ETGs have been analyzed by both Blancato et al. (2017) and Barber et al. (2019b), who find that their simulated present-day ETGs have broadly realistic $\alpha_{IMF}$ profiles. In the case of Barber et al. (2019b), the $\alpha_{IMF}$ profiles tend to be steeper for model ‘LoM’ than for model ‘HiM’. Here we address the question of the evolution of the $\alpha_{IMF}$ gradients with a simpler approach, using binary dissipationless merging simulations, which are outside a fully cosmological framework. Though idealized in some respect, our simulations allow us to study in great detail the dynamical effects on the distribution of $\alpha_{IMF}$, which are believed to be important in the second phase of ETG formation. With our approach, we can disentangle these dynamical effects from other effects more directly related to dissipation and star formation, which is not straightforward in cosmological hydrodynamic simulations.

If the IMF is not universal, the presence of IMF gradients within ETGs must be expected, because merging produces a partial mixing of the stellar populations (White 1980). For instance, in the idealized case of a binary dissipationless merger in which the two merging galaxies have different IMF and no $\alpha_{IMF}$ gradient, an $\alpha_{IMF}$ gradient will naturally arise in the remnant. More realistically, we can envisage an evolutionary scenario for ETGs in which galaxies with $\alpha_{IMF}$ gradients merge with other galaxies that have themselves $\alpha_{IMF}$ gradients and generally different average $\alpha_{IMF}$. This is the approach we adopt in the models here presented.

The paper is organized as follows. The set-up and the analysis of the $N$-body simulations are described in Section 2 and Section 3, respectively. Our results are presented in Section 4. Section 5 concludes.

2 N-BODY SIMULATIONS

2.1 Sets of simulations

In this paper we analyze $N$-body simulations of binary dissipationless galaxy mergers presented in previous works. In particular, we focus on ten simulations taken from the simulation sets named D, D3 and D4 in Sonnenfeld, Nipoti & Treu (2014), some of which were originally presented in Nipoti et al. (2009) and Nipoti et al. (2012).

The six simulations of set D are characterized by different values of the stellar mass ratio $\xi_\star = M_{\star, \text{sat}}/M_{\star, \text{main}}$ between the two progenitor galaxies: two with $\xi_\star = 1$ (equal-mass major merger), two with $\xi_\star = 0.5$ (unequal-mass major merger) and two with
\( \xi_s = 0.2 \) (minor\(^2\) merger). Here \( M_{\text{main}} \) is the stellar mass of the more massive progenitor galaxy (hereafter referred to as main galaxy) and \( M_{\text{sat}} \leq M_{\text{main}} \) is the stellar mass of the less massive progenitor galaxy (hereafter referred to as satellite galaxy). Throughout the paper the subscripts ‘main’, ‘sat’ and ‘remn’ indicate quantities relative to the main galaxy, to the satellite galaxy, and to the merger remnant, respectively.

The main galaxy is modelled as a two-component spherically symmetric stellar system with a stellar component and a dark matter (DM) halo. This model is described in Section 2.2. In the case of equal-mass mergers (\( \xi_s = 1 \)) the satellite galaxy is identical to the main galaxy. In the case of unequal-mass mergers (\( \xi_s < 1 \)) set D, the satellite galaxy is a smaller-scale replica of the main galaxy, i.e. it is structurally and kinematically homologous (see e.g. section 5.4 of Cimatti et al. 2019) to the main galaxy, but has different mass and length scale, depending on \( \xi_s \) (see Section 2.2). In the simulations of set D3 and D4 (all with \( \xi_s = 0.2 \)) the satellite galaxy is not homologous to the main galaxy (see Section 2.2).

In all the simulations considered here the mergers are parabolic (i.e. with zero orbital energy in the point-mass-two-body approximation of the encounter). For each value of \( \xi_s \) and each set (D, D3 and D4), we have two simulations, one with zero orbital angular momentum (\( r_{\text{peri}} = 0 \); hereafter referred to as head-on merger simulations) and the other with non-zero orbital angular momentum (\( r_{\text{peri}} \neq 0 \); hereafter referred to as off-axis merger simulations), where \( r_{\text{peri}} \) is the pericentric radius. In Table 1, where the main parameters of the simulations are reported, the orbital angular momentum is quantified by the ratio \( r_{\text{peri}} / r_{\text{vis}} \), where \( r_{\text{vis}} \) is the virial radius of the main galaxy. We note that the values of \( r_{\text{peri}} / r_{\text{vis}} \) used for our off-axis merger simulations are close to the median values found for halo-halo mergers in cosmological simulations (e.g. Wetzel 2011), which suggests that the off-axis simulations could be more representative of cosmologically motivated mergers than the head-on simulations. For further details on the set-up of the initial condition we refer the reader to Sonnenfeld et al. (2014) and previous papers (Nipoti et al. 2009, 2012) from which some simulations were collected.

\(^2\) Mergers are usually classified as minor when the mass ratio is lower than either 1/3 or 1/4.

### Table 1. Parameters of the galaxy encounters, of the progenitor galaxy models and of the merger remnants in the dissipationless binary-merger \( N \)-body simulations analyzed in this work. Name: name of simulation. Set: name of the simulation set. \( M_{\text{DM}} \): total DM mass. \( M_{\star} \): total stellar mass. c: NFW concentration. \( r_c \): NFW scale radius. \( R_c \): effective radius. \( \xi = M_{\text{sat}} / M_{\text{main}} \): stellar mass ratio. \( r_{\text{peri}} / r_{\text{vis}} \): pericentric-to-virial ratio (\( r_{\text{vis}} \) is the virial radius of the main galaxy), quantifying the orbital angular momentum of the encounter (all encounters are parabolic). \( \alpha_{\text{DM}}, \beta_{\text{DM}} \) and \( C_{\text{DM}} \): parameters used in post-processing to assign \( \rho_{\text{DM}} \) to particles (equations 7 and 8). Here \( R_{\text{c,DM}} \equiv R_{\text{c,DM,main}} \), \( \sigma_{\text{DM}} \equiv \sigma_{\text{DM,main}} \), \( \sigma_{\text{DM,remn}} \equiv \sigma_{\text{DM,remn}} \equiv \sigma_{\text{DM,remn,main}} \), \( \sigma_{\text{DM,remn,main}} \equiv \sigma_{\text{DM,remn,main}} \). In all cases \( M_{\text{DM}} / M_{\text{main}} = 49 \) and \( r_{\text{vis}} / R_{\text{vir,main}} = 11.6 \). Subscripts ‘main’, ‘sat’ and ‘remn’ refer to the main galaxy, the satellite galaxy and the remnant, respectively.

### 2.2 Progenitor galaxy models

The stellar density distribution of the progenitor galaxies is represented by a \( \gamma \) model (Dehnen 1993; Tremaine et al. 1994) with \( \gamma = 3/2 \):

\[
\rho_{\text{DM}}(r) = \frac{M_{\star} r_{\star}}{8 \pi r^2 (r + r_{\star})^{3/2}},
\]

where \( M_{\star} \) is the total stellar mass and \( r_{\star} \) is the characteristic radius of the stellar component. The DM halo is described by a Navarro, Frenk & White (1996, NFW) model, so the DM density distribution is

\[
\rho_{\text{DM}}(r) = \frac{M_{\text{DM}}}{4 \pi r^2 dr} \exp \left[ -\frac{r}{r_{\text{vir}}} \right],
\]

where \( r_{\text{vir}} \) is the scale radius, \( M_{\text{DM}} \) is a reference mass and we adopt an exponential cut-off to truncate the distribution smoothly at the virial radius \( r_{\text{vir}} \), so the total DM mass \( M_{\text{DM}} = 4 \pi \int_0^{r_{\text{vir}}} \rho_{\text{DM}}(r) r^2 dr \) is finite. We assume Osipkov-Merritt (Osipkov 1979; Merritt 1985) anisotropy in the velocity distribution of the stellar component, whose distribution function is then given by

\[
f(Q) = \frac{1}{\sqrt{8 \pi^2}} \frac{d}{dQ} \int_0^Q \frac{d\rho_s}{d\Psi_{\text{tot}}} \frac{d\Psi_{\text{tot}}}{\sqrt{Q - \Psi_{\text{tot}}}},
\]

where

\[
\rho_s(r) = \left( 1 + \frac{r_{\star}^2}{r^2} \right) \rho_{\text{DM}}(r).
\]

The variable \( Q \) is defined as \( Q \equiv E - L^2 / 2 c_s^2 \), where the relative (positive) energy is given by \( E \equiv \Psi_{\text{tot}} - v^2 / 2 \), \( v \) is the modulus of the velocity vector, the relative (positive) total potential is \( \Psi_{\text{tot}} = \Psi_s + \Psi_{\text{DM}} \) (\( \Psi_s \) and \( \Psi_{\text{DM}} \) are, respectively, the relative potentials of the stellar and DM components), \( L \) is the angular momentum modulus per unit mass, and \( f(Q) = 0 \) for \( Q \leq 0 \). The quantity \( r_{\star} \) is the so-called anisotropy radius: for \( r > r_{\star} \) the velocity dispersion tensor is radially anisotropic, while for \( r < r_{\star} \), the tensor is nearly isotropic. In the limit \( r_{\star} \to \infty \), \( Q = E \) and the velocity dispersion tensor is globally isotropic.

The orbital distribution of the DM halo is assumed isotropic, so the distribution function of the DM component is given by equation (5) where \( Q = E \) and \( \rho_{\text{DM}}(r) \) substitutes \( \rho_s(r) \). These
The line-of-sight stellar velocity dispersion profile \( \sigma_{\text{los}}(R) \) is defined by

\[
\sigma_{\text{los}}^2(R) = \frac{1}{\Sigma(R)} \int f(Q) (v_{\text{los}} - \overline{v}_{\text{los}})^2 d\Sigma, \quad (11)
\]

where \( v_{\text{los}} \) is the line-of-sight velocity, \( \overline{v}_{\text{los}} \) is the mean of \( v_{\text{los}} \) and \( r_R \) is a vector representing the velocity components in the plane of the sky. The effective velocity dispersion, i.e. the stellar mass-weighted line-of-sight central stellar velocity dispersion measured within a circle of radius \( R_e \), is given by

\[
\sigma_e^2 = 2\pi \int_0^{R_e} \frac{\int_0^\infty \Theta(R) \sigma_{\text{los}}^2(R) R dR}{M_*/2}. \quad (12)
\]

We note that \( \sigma_e \) in observed galaxies is a luminosity-weighted quantity, while here for simplicity we have defined it for our galaxy models as a mass-weighted quantity. Strictly speaking, the two definitions differ because we are considering systems with gradients in \( \sigma_{\text{los}} \) and thus in \( M_*/L \) (see Bernardi et al. 2018), but this difference is expected to be small, especially for our models in which \( \sigma_{\text{los}} \) varies at most by \( \approx 20\% \) at \( R \approx R_e \) (Section 4.1). The projected \( \sigma_{\text{los}} \) profile is

\[
\alpha_{\text{los}}(Q) = \frac{1}{\Sigma(R)} \int \sigma_{\text{los}}(Q) f(Q) d\Sigma, \quad (13)
\]
We define the effective IMF mismatch parameter as the mass-weighted projected \( \alpha_{\text{IMF}} \) within \( R_e \), i.e.

\[
\alpha_e = \frac{2\pi \int_0^{R_e} \Sigma(R) v_{\text{IMF}}(R) R dR}{M_*/2}.
\] (14)

### 3.2.2 N-body systems

The projected properties of our \( N \)-body models are computed as in Nipoti et al. (2006) and Nipoti et al. (2009). In particular, for any given line of sight, having determined the ellipticity \( \epsilon \) and the principal axes of the stellar surface density distribution, we measure all the projected quantities considering concentric elliptical annuli all with the same ellipticity \( \epsilon \). The \( k \)-th annulus is characterized by its average circularized radius \( R_k \), such that \( \log R_{k+1} - \log R_k \approx \Delta x \) with \( \Delta x \) = constant for all \( k \). The effective radius \( R_e \) is computed as the circularized radius of the ellipse containing half of the stellar particles in projection. The line-of-sight velocity dispersion at \( R_k \) is computed as

\[
\sigma_{\text{los}}(R_k) = \left[ \frac{1}{N_k} \sum_i (v_{\text{los},i} - \bar{v}_{\text{los}})^2 \right]^{1/2},
\] (15)

where \( v_{\text{los},i} \) is the line-of-sight velocity dispersion of the \( i \)-th particle, the sum is over all the \( N_k \) stellar particles belonging to the \( k \)-th projected annulus and \( \bar{v}_{\text{los}} \) is the mean line-of-sight velocity of these \( N_k \) particles (the total number of stellar particles is \( N = \sum_k N_k \)). The effective velocity dispersion is computed as

\[
\sigma_e = \left[ \frac{2}{N} \sum_i (\bar{v}_{\text{los},i} - \bar{v}_{\text{los}})^2 \right]^{1/2},
\] (16)

where \( \bar{v}_{\text{los}} \) is the mean line-of-sight velocity of the \( N/2 \) stellar particles contained within the ellipse with circularized radius \( R_e \) and the sum is over the same \( N/2 \) particles.

We compute the radial profile of the IMF mismatch parameter as

\[
\alpha_{\text{IMF}}(R_k) = \frac{1}{N_k} \sum_i \alpha_{\text{IMF},i},
\] (17)

where \( \alpha_{\text{IMF},i} \) is the value of \( \alpha_{\text{IMF}} \) of the \( i \)-th particle, and the sum is over all the \( N_k \) stellar particles belonging to the \( k \)-th annulus. The effective IMF mismatch parameter is computed as

\[
\alpha_e = \frac{2}{N} \sum_i \alpha_{\text{IMF},i},
\] (18)

where the sum is over all the \( N/2 \) stellar particles contained within the ellipse with circularized radius \( R_e \).

For each \( N \)-body system we consider 50 projections with different (random) lines of sight and we compute the mean and standard deviation of \( \sigma_{\text{los}}(R/R_e) \), \( \sigma_e \), \( \alpha_{\text{IMF}}(R/R_e) \) and \( \alpha_e \).

### 3.3 Physical units and normalizations

Given the scale-free nature of gravity, our dissipationless merging simulations are fully scalable in mass and length. We take as mass unit \( M_0 = M_{\text{max}} \), the stellar mass of the main galaxy and as length unit \( \ell_0 = r_{\text{max}} \), the stellar scale radius of the main galaxy. Thus, for the adopted main galaxy model (Section 2.2), the effective radius of the main galaxy is

\[
R_{e,\text{main}} \approx 1.23 \left( \frac{\ell_0}{\text{kpc}} \right) \text{kpc}
\] (19)

As far as the IMF mismatch parameter is concerned, we normalize all our results to \( \alpha_{e,\text{main}} \), the value of \( \alpha_e \) of the main galaxies. The value of \( \alpha_{e,\text{main}} \) is independent of both \( M_0 \) and \( \ell_0 \), and can be chosen freely if one wants to apply our results to specific observational targets. We recall that for an ensemble of stellar particles, the quantity \( \alpha_{\text{IMF}} \) used in this paper is the true \( M_0/L \) normalized to the \( M_*/L \) of a reference IMF (equation 1). Our results can be interpreted by choosing freely the reference IMF: for instance a Salpeter, a Kroupa or a Chabrier IMF.

### 4 RESULTS

Here we present the results on the evolution of \( \alpha_{\text{IMF}} \) in mergers based on the dissipationless binary merging simulations described in Section 2. In order to assign values of \( \alpha_{\text{IMF}} \) to particles, we have to choose, in post-processing, the values of the coefficients...
3.2.2 Falcón-Barroso et al. (2017) we note that Raskutti et al. (2014) the IMF mismatch parameter of the main progenitor galaxy.

The results presented in this section refer to simulations (set D in Section 3.1). We present here results obtained adopting $A_{\text{IMF}}, B_{\text{IMF}}$ and $C_{\text{IMF}}$ that depends on $\xi_e$ (the specific values of $C_{\text{IMF}}$ are reported in Table 1). In Sections 4.2 and 4.3 we show that with this choice we obtain progenitor galaxy models with realistic $\alpha_{\text{IMF}}$ profiles. We experimented with different choices of the values of $A_{\text{IMF}}, B_{\text{IMF}}$ and $C_{\text{IMF}}$, finding that, provided that the values give realistic $\alpha_{\text{IMF}}$ profiles in the progenitors, the merger-driven evolution of the $\alpha_{\text{IMF}}$ profiles is weakly dependent on the specific choice of $A_{\text{IMF}}, B_{\text{IMF}}$ and $C_{\text{IMF}}$. In Appendix A, we show examples illustrating the effect of choosing values of $A_{\text{IMF}}$ and $B_{\text{IMF}}$ giving significantly different $\alpha_{\text{IMF}}$ profiles for the progenitors. The results presented in this section refer to simulations (set D in Table 1) in which the main and satellite galaxies are structurally and dynamically homologous (see Section 2.1). In Appendix B we compare some of these simulations with analogous simulations in which the satellite and the progenitor galaxies are not homologous, finding results very similar to those presented in this section.

The profiles of $\sigma_{\text{los}}$ and $\sigma_{\text{IMF}}$, as well as the integrated quantities $\sigma_e$ and $\alpha_e$, depend on the line of sight. In this section, we show for each N-body system a single value of each of these quantities, that is the mean over 50 different lines of sight. In some cases we associate to this mean, as an error bar, the corresponding standard deviation (see Section 3.2.2).

4.1 Velocity dispersion profiles

The stellar line-of-sight velocity dispersion profiles of the progenitor galaxies and of the remnants of the simulations are shown in the upper panels of Figs. 1-3. In the main galaxy (hexagons in Figs. 2-3), the decrease in $\sigma_{\text{los}}$ is about 20%, broadly consistent with the observed profiles of ETGs (e.g. de Zeeuw et al. 2002; Falcón-Barroso et al. 2017), but we note that in our model such a positive gradient is limited to very small radii ($R \leq 0.2R_e$), not always probed in spectroscopic observations. In fact, the inner $\sigma_{\text{los}}$ profile of the progenitors is very shallow ($\sigma_{\text{los}}$ increases by $\approx 10\%$ from $R \approx 0.02R_e$ to $R \approx 0.2R_e$), so we do not expect this feature of our progenitor galaxy models to affect the main conclusions of our work. From the peak to $R_e$, the decrease in $\sigma_{\text{los}}$ is about 20%, broadly consistent with the observed profiles of ETGs (see e.g. Raskutti et al. 2014; Veale et al. 2018). The satellite galaxies in the unequal-mass mergers (pentagons in Figs. 2-3) are homologous to the main galaxy, so they have $\sigma_{\text{los}}$ profiles with the same shape as that of the main, but just scaled down to lower values of velocity dispersion.

Figure 2. Same as Fig. 1, but for the merging simulations with stellar mass ratio $\xi_e = 0.5$. The hexagons and pentagons represent, respectively, the main and satellite progenitor galaxies. The remnants are indicated with squares (simulation 0.5Dh) and circles (simulation 0.5Dh). $R/R_{e,\text{main}}, \sigma/\sigma_{e,\text{main}}$ and $\alpha_{\text{e,main}}$ are, respectively, the effective radius, velocity dispersion and IMF mismatch parameter of the main progenitor galaxy.

Figure 3. Same as Fig. 2, but for the remnants of the $\xi_e = 0.2$ merging simulations with stellar mass ratio 0.2Dh (squares) and 0.2Dh (circles), and for their main (hexagons) and satellite (pentagons) progenitor galaxies.
The remnants of the equal-mass mergers (Fig. 1) have line-of-sight velocity dispersion comparable to or higher than that of the progenitors at all radii: we find that $\sigma_{\text{los}}$ increases more in the off-axis than in the head-on merger, as found in general in dissipationless mergers (e.g., Boylan-Kolchin et al. 2006; Nipoti et al. 2009). The remnants of unequal-mass mergers (Figs. 2-3) have lower $\sigma_{\text{los}}$ profiles than those of the equal-mass mergers. The lowest $\sigma_{\text{los}}$ profile is obtained for the remnant of the head-on minor merger ($\xi_\star = 0.2$). Focusing on the central parts of the velocity dispersion profiles, we notice that the behaviour of $\sigma_{\text{los}}$ in the remnant ranges from being higher (as in the off-axis $\xi_\star = 1$ merger) to being lower (as in the head-on $\xi_\star = 0.2$ merger) than $\sigma_{\text{los}}$ in the main progenitor.

In Figs. 1-3 $\sigma_{\text{los}}$ and $R$ are normalized, respectively, to the effective velocity dispersion $\sigma_{\text{e,main}}$ and to the effective radius $R_{e,\text{main}}$ of the main progenitor galaxy for both the progenitors and the remnants, so all the $\sigma_{\text{los}}$ profiles are shown on the same physical scale. These profiles can be converted in physical units by fixing $M_\odot$ and $\xi_\star$ (see Section 3.3): an example is given in the upper panel of Fig. 4, showing the $\sigma_{\text{los}}$ profiles of the main progenitor and of the remnants of the same six simulations as in Figs. 1-3. When interpreting the variations in the $\sigma_{\text{los}}$ profiles shown in Figs. 1-4 one must bear in mind that, as well known, dry mergers make galaxies more diffuse (see values of $R_{e,\text{main}}$ in Table 1), so the effect of mergers is not only to change the shape of the $\sigma_{\text{los}}$ profiles, but also to “stretch” them horizontally. To isolate the effect of the mergers on the shape of the $\sigma_{\text{los}}$ profiles, it is useful to normalize $R$ and $\sigma_{\text{los}}$ of each system (either progenitor or remnant) to, respectively, their own $R_e$ and $\sigma_{\text{los}}$ at $R_e$, as done in the upper panel of Fig. 5. The main effect of the mergers on the shape of the $\sigma_{\text{los}}$ profile is an overall flattening of the profile. We also note that the positive central $\sigma_{\text{los}}$ gradient of the progenitor tends to be erased by the merging.

### 4.2 Initial mass function mismatch parameter profiles

The stellar IMF mismatch parameter profiles of the progenitor galaxies and of the remnants of the simulations are shown in the lower panels of Figs. 1-3. In the progenitor galaxies (hexagons and pentagons in the plots) $\alpha_{\text{IMF}}$ decreases monotonically with radius, by a factor of about two from the centre to $\sim 3R_e$, consistent with the observational estimates of present-day ETGs (e.g., La Barbera et al. 2019). We note that, given that by construction
$A_{\text{IMF}}$ and $B_{\text{IMF}}$ are the same in the two progenitor galaxies, the $\alpha_{\text{IMF}}$ profile of the satellite galaxy (pentagons) is just a scaled-down version of that of the main galaxy (hexagons): specifically, at given $R/R_*$, $\alpha_{\text{IMF, sat}} = C_{\text{IMF}}\alpha_{\text{IMF, main}}$, with $C_{\text{IMF}} \leq 1$.

Let us focus first on equal-mass mergers (Fig. 1). The merger remnant has, with respect to the progenitor galaxies, a shallower central gradient of $\alpha_{\text{IMF}}$. The remnant’s $\alpha_{\text{IMF}}$ profile is very similar for off-axis (circles) and head-on (squares) encounters. Moving to unequal-mass major ($\xi_* = 0.5$; Fig. 2) and minor ($\xi_* = 0.2$; Fig. 3) mergers, we note that the main effect of the merger is to flatten the central gradient of $\alpha_{\text{IMF}}$ by producing a central ‘core’ of constant $\alpha_{\text{IMF}}$ with size ranging from $\approx 0.1$ to $\approx 0.3$ in units of $R_{\text{e,main}}$. The core is produced by the lower-$\alpha_{\text{IMF}}$ stellar particles of the satellite that settle in the central regions and mix with the higher-$\alpha_{\text{IMF}}$ stellar particles of the main. For major mergers ($\xi_* = 0.5$) the core is larger for head-on (squares) than for off-axis (circles) encounters, while for minor mergers ($\xi_* = 0.2$) the core is larger for off-axis than for head-on encounters, which suggests that mixing and accretion of satellite’s stars in the central region of the remnant depends on a non-trivial way both on the orbit of the encounter and on the merger mass ratio, for given structural properties of the progenitors.

The $\alpha_{\text{IMF}}$ profiles shown in Figs. 1-3 are all on the same physical scale, because $\alpha_{\text{IMF}}$ and $R$ are normalized, respectively, to the effective IMF mismatch parameter $\alpha_{\text{e,main}}$ and to effective radius $R_{\text{e,main}}$ of the main progenitor. In the lower panel of Fig. 4, the $\alpha_{\text{IMF}}$ profiles of the main progenitor and of the remnants are shown in physical units, for a representative case in which we have assumed $\alpha_{\text{e,main}} = 1.15$ and the Salpeter IMF as reference. As done for the $\sigma_{\text{los}}$ profiles (Section 4.1), in Fig. 5 (lower panels) we show the same $\alpha_{\text{IMF}}$ profiles as in Fig. 4, but normalized to $R_e$ and $\sigma_{\text{los}}(R_e)$, to highlight the variations in the shape of the profiles, which are significant only at $R \lesssim R_e$. In Figs. 1-4 the remnants have higher $\alpha_{\text{IMF}}$ than the progenitor at large radii mainly because of the merger-driven size evolution: on average, stars originally belonging to the main progenitor orbit at larger (physical) radius in the remnant.

Overall, under the considered hypotheses (heavier average IMF in more massive progenitors and negative radial gradients of $\alpha_{\text{IMF}}$ in the progenitors), the effect of dissipationless mergers is invariably to redistribute $\alpha_{\text{IMF}}$ by reducing it in the central regions and slightly increasing it at large radii, thus weakening the $\alpha_{\text{IMF}}$ gradient. We note that this weakening of the $\alpha_{\text{IMF}}$ gradient is not a necessary consequence of merging with a lower-$\alpha_{\text{IMF}}$ satellite, but it must be expected when the $\alpha_{\text{IMF}}$ gradient in the main progenitor is sufficiently strong and when the satellite is sufficiently compact not to be completely disrupted in the outskirts of the main. If the main progenitor had a negligible $\alpha_{\text{IMF}}$ gradient, a merger with a low $\alpha_{\text{IMF}}$ satellite could give rise to $\alpha_{\text{IMF}}$ profiles with both positive and negative $\alpha_{\text{IMF}}$ gradients (see Section 1). The effect of dry merging on the $\alpha_{\text{IMF}}$ profiles depends also on the structural properties of the satellite (see Section 4.5.1). The accretion of loose (low-density) satellites with low $\alpha_{\text{IMF}}$ can produce a negative radial gradient of $\alpha_{\text{IMF}}$, because such satellites tend to deposit their stars mainly in the outer regions of the remnant, while the central $\alpha_{\text{IMF}}$ is determined by stars formed in situ (see Smith 2020, for a discussion).

### 4.3 Local $\alpha_{\text{IMF}}$ as a function of local $\sigma_{\text{los}}$

In their study of the spatially resolved stellar IMF, Parikh et al. (2018) explored the distribution of the local $\alpha_{\text{IMF}}$ as a function of the local $\sigma_{\text{los}}$ for a large sample of ETGs (see figure 16 in that paper; see also Domínguez Sánchez et al. 2019, 2020). Here we perform a similar analysis, but for our merging simulations. In Fig. 6 we

**Figure 6.** Local (i.e. at given $R$) IMF mismatch parameter $\alpha_{\text{IMF}}$ as a function of local (at the same $R$) line-of-sight velocity dispersion $\sigma_{\text{los}}$ of the progenitor galaxies and of the remnants of simulations 1Dh and 1Do ($\xi_* = 1$, top panel), 0.5Dh and 0.5Do ($\xi_* = 0.5$, middle panel) and 0.2Dh and 0.2Do ($\xi_* = 0.2$, bottom panel) in the radial interval $0.1 \leq R/R_e \leq 1$, where $R_e = R_{\text{e,main}}$ for the main galaxy, $R_e = R_{\text{e,sat}}$ for the satellite galaxy and $R_e = R_{\text{e,rem}}$ for the remnants. Symbols and normalizations are the same as in Figs. 1-3. The size of the symbol increases for increasing $R$. 

MNRAS 000, 000–000 (0000)
plot the local $\alpha_{\text{IMF}}$ as a function of the local $\sigma_{\text{los}}$ for the remnants and the progenitor galaxies of our simulations with $\xi_\star = 1$ (top panel), $\xi_\star = 0.5$ (middle panel) and $\xi_\star = 0.2$ (bottom panel). Similar to Parikh et al. (2018), in these diagrams we plot only values of $\sigma_{\text{los}}(R)$ and $\alpha_{\text{IMF}}(R)$ lying in the radial range $0.1 \leq R/R_e \leq 1$. The bottom parts of the distributions correspond to $R \approx R_e$ (lower values of $\sigma_{\text{los}}$), while the top parts to the central regions (higher $\sigma_{\text{los}}$). The $\alpha_{\text{IMF}}$-$\sigma_{\text{los}}$ distribution of the progenitor galaxies of our simulations is qualitatively similar to that inferred for real ETGs by Parikh et al. (2018), though, quantitatively, the relative variations in $\sigma_{\text{los}}$ and $\alpha_{\text{IMF}}$ are somewhat smaller in our model galaxies than in the ETGs of Parikh et al.’s sample. In both model and real ETGs the trend is that $\alpha_{\text{IMF}}$ tends to increase with $\sigma_{\text{los}}$, but, different from the data of Parikh et al. (2018), in our progenitor galaxies the points with the highest $\sigma_{\text{los}}$ are not those with the highest $\sigma_{\text{los}}$; this reflects the fact that the $\sigma_{\text{los}}$ profiles of these models peak at $R \approx 0.2R_e$ and slightly decreases towards the centre (Fig. 4). By construction, the distribution of the satellite galaxy in the unequal-mass merger simulations is a scaled-down version of that of the main galaxy.

The $\alpha_{\text{IMF}}$-$\sigma_{\text{los}}$ distributions of the remnants are qualitatively similar to those of the progenitor galaxies. In detail, the distributions tend to be narrower in $\sigma_{\text{los}}$, because in the radial range $0.1 \leq R/R_e \leq 1$ the remnants’ $\sigma_{\text{los}}$ profiles are flatter than those of the progenitors (see upper panel of Fig. 5). Moreover, with the only exception of the $\xi_\star = 0.2$ head-on merger, the range in $\sigma_{\text{los}}$ spanned by the remnants tends to be smaller than that spanned by the progenitors, as a consequence of the mixing of the stellar populations in the central regions. The average $\sigma_{\text{los}}$ of the remnant is higher than that of the main galaxy when $\xi_\star = 1$ and lower when $\xi_\star = 0.2$. When $\xi_\star = 0.5$ the average $\sigma_{\text{los}}$ is comparable to that of the main galaxy, with a behaviour that depends in detail on the orbital angular momentum of the encounter. We note that the remnant of the head-on $\xi_\star = 0.5$ major merger has a peculiar distribution in the $\sigma_{\text{los}}$-$\alpha_{\text{IMF}}$ plane (squares in the middle panel of Fig. 6), which reflects the somewhat unusual $\sigma_{\text{los}}$ and $\alpha_{\text{IMF}}$ profiles (squares in Fig. 2). In this case the satellite reaches and modifies the central regions of the main, both inducing mixing in the existing stellar populations and depositing its own stars. The effect is strongest for intermediate mass ratios ($\xi_\star = 0.5$), because for higher mass ratios ($\xi_\star = 1$) the progenitors have the same average $\sigma_{\text{los}}$ and for lower mass ratios ($\xi_\star = 0.2$) the satellite carries a small fraction of the total stellar mass of the remnant. However, encounters with exactly zero orbital angular momentum are extreme cases, and we expect the off-axis simulations, which produce more regular distributions of $\sigma_{\text{los}}$ and $\alpha_{\text{IMF}}$, to be more realistic (see Section 2.1).

We note that in figure 16 of Parikh et al. (2018), which is based on a sample of present-day ETGs, more massive galaxies have higher average $\sigma_{\text{los}}$, as it is usual. In our minor merger simulations (bottom panel of Fig. 6) the remnants have lower average $\sigma_{\text{los}}$ than their main progenitors, which are naturally less massive. This result is not necessarily in contrast with the observational data, because it must be put in the context of galaxy evolution (see Sections 4.4.4.5): we recall that the observed $M_\star$-$\sigma$ relation of ETGs evolves with redshift in the sense that, at given $M_\star$, $\sigma$ tends to be higher at higher $z$ (see Cannarozzo et al. 2020, and references therein).

### 4.4 Effect of dry mergers on $\sigma_\star$ and $\alpha_\star$

We move here to study the effect of the considered dissipation-less mergers on the global galaxy properties: the effective IMF mismatch parameter $\alpha_e$ and the effective velocity dispersion $\sigma_e$.

Figure 7. Effective IMF $\alpha_e$ (normalized to $\alpha_\star$ of the main progenitor galaxy) as a function of effective velocity dispersion $\sigma_e$ (normalized to $\sigma_\star$ of the main galaxy) for the remnants of simulations 1Dh (head-on, $\xi_\star = 1$), 1Do (off-axis, $\xi_\star = 0.5$), 0.5Do (off axis, $\xi_\star = 0.5$), 0.2Dh (head-on, $\xi_\star = 0.2$) and 0.2Do (off axis, $\xi_\star = 0.2$), and of their main (hexagons) and satellite (pentagons) progenitor galaxies (in the case $\xi_\star = 1$ the satellite progenitor galaxy is identical to the main galaxy, and both are represented by the hexagon). The remnants of head-on and off-axis merging simulations are represented, respectively, by squares and circles, whose size is larger for higher stellar-mass ratios $\xi_\star$. The error bars indicate 1σ scatter on the effective velocity dispersion due to projection effects on the remnants (the 1σ scatter in effective IMF mismatch parameter is comparable to or smaller than the symbol size). The arrows connect the position of the main galaxy with those of the remnants and thus indicate the transformations produced by the mergers on the main galaxy. The grey line indicates the slope of the observational $\alpha_e$-$\sigma_e$ relation as determined by Posacki et al. (2015) for a sample of present-day ETGs (equation 2). We note that the scatter of the observational relation, 0.12 dex in $\alpha_e$ at given $\sigma_e$, is comparable to extent of the vertical axis of the plot.

Figure 8. Same as Fig. 7, for the same simulations, but now $\alpha_e$ and $\sigma_e$ are normalized to values $\alpha_{e,\text{remn}}$ and $\sigma_{e,\text{remn}}$ measured for the remnants. By definition the remnant, represented by a star, lies at $\sigma_{e,\text{remn}}/\sigma_{e,\text{remn}} = 1$ and $\alpha_{e,\text{remn}}/\alpha_{e,\text{remn}} = 1$. The progenitors are indicated with squares for head-on mergers and circles for off-axis mergers, of size increasing with $\xi_\star$. Error bars on the positions of the main progenitors are due to 1σ projection-effect scatter on the remnant’s effective velocity dispersion. Here the satellite galaxies are not shown. The grey solid line indicates the observed present-day $\alpha_e$-$\sigma_e$ relation (equation 2). The arrows have the same role as in Fig. 7.
Fig. 7 shows the behaviour of our simulations in the $\sigma_e$-$\sigma_*$ plane in which $\sigma_e$ is normalized to $\sigma_{e,\text{main}}$ and $\sigma_*$ to $\sigma_{*,\text{main}}$. By construction (i.e. as a consequence of our choice of the parameter $C_{\text{IMF}}$), the main galaxy (hexagon) and the satellite galaxies (pentagons) lie on a power law $\sigma_e \propto \sigma_*^{\alpha}$ with the same slope as the correlation (equation 2) observed for present-day ETGs. The remnants (squares and circles with error bars) have in all cases $\alpha_e$ lower than that of the main progenitor, which is an expected consequence of the flattening of the $\alpha_e$ gradient in the equal-mass mergers and also of the accretion of a lower-$\alpha_e$ galaxy in the unequal-mass mergers. The final value of $\alpha_e$ depends more on the mass ratio than on the orbital angular momentum of the encounter. The lowest values of $\alpha_e$ are obtained in the $\xi_e = 0.5$ major merger, while the remnants of the $\xi_e = 0.2$ minor mergers have $\alpha_e$ intermediate between the $\xi_e = 1$ and the $\xi_e = 0.5$ major mergers. The effect on $\sigma_e$ is variegated, ranging from equal-mass mergers that make $\sigma_e$ increase to minor mergers that make $\sigma_e$ decrease. With the only exception of the head-on $\xi_e = 0.2$ merger (arrow pointing towards the smallest square in Fig. 7), for which the remnant lies on the same $\alpha_e$-$\sigma_e$ power law followed by the progenitor galaxies, the effect of the dry merging is to move the galaxies away from the $\alpha_e$-$\sigma_e$ relation, producing remnants with lower $\alpha_e$ for their $\sigma_e$ (compared to the progenitor galaxies). The error bars in Fig. 7 give a measure of the projection effects in $\sigma_e$, due to the fact that the remnants are not spherically symmetric (the projection effects on $\alpha_e$ turn out to be negligible). We note that these projection effects are well within the intrinsic scatter of the observed correlation, which is $\approx 0.1$ dex in $\alpha_e$ at given $\sigma_*$ (see Section 1) and thus, given the slope of the relation (equation 2), $\approx 0.3$ dex in $\sigma_e$ at given $\alpha_e$.

In order to compare quantitatively the effect on $\sigma_e$ and $\alpha_e$ of mergers with different $\xi_e$, it is useful to introduce the quantities

$$\gamma_e = \frac{\log \sigma_{e,\text{remn}} - \log \sigma_{e,\text{main}}}{\log M_{e,\text{remn}} - \log M_{e,\text{main}}}$$

and

$$\gamma_o = \frac{\log \sigma_{o,\text{remn}} - \log \sigma_{o,\text{main}}}{\log M_{o,\text{remn}} - \log M_{o,\text{main}}} = \frac{\log \sigma_{e,\text{remn}}}{\log(1 + \xi_e)} \left(1 + \xi_e\right),$$

which measure the variations of, respectively, $\log \sigma_e$ and $\log \alpha_e$ per unit logarithmic stellar mass increase (the values of $\sigma_{e,\text{remn}}$ and $\alpha_{e,\text{remn}}$ are given for each simulation in Table 1; we have used $M_{e,\text{remn}}/M_{e,\text{main}} = 1 + \xi_e$, because the stellar mass loss turns out to be negligible in the considered mergers). In our set-D simulations we find $-0.48 \leq \gamma_e \leq 0.11$ and $-0.16 \leq \gamma_o \leq -0.03$, where the lowest values are for $\xi_e = 0.2$ and the highest for $\xi_e = 1$.

For a more direct comparison with observational data, we plot in Fig. 8 a $\sigma_e$-$\alpha_e$ diagram in which the remnants are assumed to lie on the observed present-day $\alpha_e$-$\sigma_e$ relation (solid line). Note that, different from Fig. 7, in Fig. 8 we normalize $\alpha_e$ to $\sigma_{e,\text{remn}}$ and $\sigma_e$ to $\sigma_{*,\text{remn}}$ so, by construction, all the remnants are at the same point, which is assumed to lie on the observed present-day $\alpha_e$-$\sigma_e$ relation. In Fig. 8 the circles and squares indicate the positions of the main galaxies of the simulations, assuming for $\sigma_{e,\text{remn}}$ and $\alpha_{e,\text{remn}}$ the mean values measured over all the considered projections of the corresponding remnants, and the error bars, as in Fig. 7, give a measure of the projection effects due to deviations from spherical symmetry. In Fig. 8 the squares and the circles can be considered the progenitors of present-day ETGs that lie on the observed $\alpha_e$-$\sigma_e$ relation. All the progenitors, but that of the head-on $\xi_e = 0.2$ merger, lie above the $\alpha_e$-$\sigma_e$ relation.

### 4.5 Merger-driven evolution of the $\alpha_e$-$\sigma_e$ relation

We recall that so far we have not considered the effects of full merging hierarchies, but only the effects of single binary mergers. Here we attempt to predict the cosmological evolution of the $\alpha_e$-$\sigma_e$ relation based on the results of our simulations.

#### 4.5.1 Purely dry merging hierarchies

When cosmologically motivated merging hierarchies are considered, massive galaxies in the redshift range $0 \leq z \leq 2$ experience merging histories with average mass-weighted merger stellar mass ratio $\langle \xi \rangle$ in the range $0.3 \leq \langle \xi \rangle \leq 0.5$ (Sonnenfeld et al. 2017). We thus expect that in a cosmologically motivated merging history a massive ETG moves in the $\sigma_e$-$\alpha_e$ plane along a direction which is in between those of the $\xi_e = 0.2$ and $\xi_e = 0.5$ simulations (arrows starting from small and intermediate circles and squares in Fig. 8).

Given that in our model the satellite and main galaxies lie on a $\alpha_e$-$\sigma_e$ power law with the same slope as that observed at $z \approx 0$, our results suggest a possible scenario in which the $\alpha_e$-$\sigma_e$ relation evolves by maintaining its slope and changing its normalisation: at given $\sigma_e$, $\alpha_e$ is higher at higher redshift. Such a scenario is qualitatively represented in Fig. 9. While $\alpha_e$ invariably decreases in this model, the evolution of $\sigma_e$ is more uncertain: even limiting to simulations with $\xi_e = 0.2$ and $\xi_e = 0.5$, bracketing the cosmologically motivated value of $\langle \xi \rangle$, $\sigma_e$ decreases in some cases and increases in others.

Let us consider an individual galaxy that experiences a merging hierarchy that produces an increase in stellar mass $\Delta \log M_*$; the corresponding variations in $\alpha_e$ and $\sigma_e$, are given by $\Delta \log \sigma_e = \Delta \log M_* \langle \gamma_e \rangle$ and $\Delta \log \alpha_e = \Delta \log M_* \langle \gamma_o \rangle$, where $\langle \cdot \cdot \cdot \rangle$ indicates the average over the merging history. Given the expected values of $\langle \xi \rangle$, we can build a toy model by estimating these averages as the mean values obtained for our four set-D simulations with either $\xi_e = 0.5$ or $\xi_e = 0.2$: $\langle \gamma_e \rangle = -0.135$ and $\langle \gamma_o \rangle = -0.123$. The thick yellow arrows in Fig. 9 indicate the effect of these variations for individual galaxies increasing their stellar masses by a factor of three as a consequence of dry mergers and ending up on the mean observed $\alpha_e$-$\sigma_e$ relation at $z \approx 0$. Given that a factor of three increase in stellar mass is expected from $z \approx 2$ to $z \approx 0$ (e.g. Sonnenfeld et al. 2017), we can interpret the starting points of the arrows as $z \approx 2$. In the hypothesis that ETGs over the entire $\sigma_e$ range have experienced similar accretion histories, the net effect of the evolution of individual galaxies is that at higher redshift the $\alpha_e$-$\sigma_e$ had similar slope but higher normalisation (at given $\sigma_e$, $\alpha_e$ is predicted to be higher at higher $z$; solid and dashed thick lines in Fig. 9). We note that, though the variation in stellar mass is as high as a factor of three, the predicted variation in the normalisation of the $\alpha_e$-$\sigma_e$ relation is just $0.04$ dex, much smaller than the intrinsic scatter of the present-day relation ($0.12$ dex; thin dotted lines in Fig. 9).

We recall that in our simulations the satellite and main galaxies are assumed to follow $R_e$-$M_*$ and $\sigma_e$-$M_*$ relations with slopes similar to those observed for massive ETGs (Section 2.2): in this sense the satellites can be considered compact, following the terminology of Hilz et al. (2013). This choice is consistent with the fact that in the present-day Universe the $R_e$-$M_*$ and $\sigma_e$-$M_*$ relations are found to be similar for central and satellite galaxies (Spinder & Wake 2017; Wang et al. 2020). However, the properties of satellite galaxies at higher $z$ are poorly constrained, so it is not excluded that the accreted satellites can be diffuse, i.e. having lower $\sigma_e$ and larger $R_e$ for their stellar mass (Hilz et al. 2013).
The assumption of compact satellites might be observationally motivated by the fact that there is no evidence of evolution of the slopes of the $R_e$-$M_e$ and $\sigma_e$-$M_e$ relations (van der Wel et al. 2014; Cannarozzo et al. 2020), though a steepening of the $\sigma_e$-$M_e$ relation with increasing redshift is not excluded (Cannarozzo et al. 2020), which might instead favour the hypothesis of diffuse satellites.

Dissipationless mergers with diffuse satellites have been studied with N-body simulations by Hilz et al. (2013). Based on the results of Hilz et al.’s simulations and on well-known properties of interacting stellar systems, it is easy to predict qualitatively how the dry-merger driven evolution of galaxies in the $\sigma_e$-$R_e$ plane changes if the accreted satellites are diffuse. A diffuse satellite, being loosely bound, is easily disrupted during the merger and deposits most of its stars in the outskirts of the main galaxy, thus producing a remnant with central $\alpha_{IMF}$ similar to the progenitor and lower $\alpha_{IMF}$ in the outskirts (thus steepening the original $\alpha_{IMF}$ gradient). As a consequence, $\alpha_e$ of the remnant will be only slightly lower than that of the main progenitor. Because of the accretion of loosely bound stars, the velocity dispersion of the remnant is lower than in the case of compact satellites (Naab et al. 2009), so $\sigma_e$ decreases more when the satellites are diffuse. Qualitatively, the net effect is that dry mergers with diffuse satellites, compared to those with compact satellites, move galaxies more horizontally in the $\sigma_e$-$R_e$ plane (thin green arrows in Fig. 9), possibly leading to a different evolution of the $\alpha_e$-$\sigma_e$ relation, with lower $\alpha_e$ at higher $z$, at given $\sigma_e$ (thin dashed line in 9).

4.5.2 The effect of dissipation and star formation

The simulations used in this work are admittedly idealized, not only because they are not within a fully cosmological context, but also because they are completely dissipationless. Present-day ETGs are poor in cold gas and have a stellar component that is dominated by old stellar populations, so if they experienced mergers in relatively recent times, these mergers must have been essentially dry. Detailed analyses of the stellar population properties of ETGs indicate that at most a few per cent of their stellar mass formed at $z \leq 1$ (e.g. Trager et al. 2000, Thomas et al. 2010; see also Sonnenfeld et al. 2014 and references therein). Though this fraction is small, such star formation could affect non-negligibly the evolution of both $\sigma_e$ and $\alpha_e$ if, as expected, it occurs in the central regions of the galaxies. Moreover, star formation might have contributed more at $z \gtrsim 1$.

Compared to purely dry mergers, slightly ‘wet’ mergers, i.e. with some dissipation and star formation, are expected to produce remnants more compact and thus with higher stellar velocity dispersion (Robertson et al. 2006; Ciotti et al. 2007; Sonnenfeld et al. 2014). The effect of dissipation and star formation on $\alpha_e$ depends on the IMF of the stars that are formed in the star formation episodes occurring during the mergers, which is of course highly uncertain. Based on the proposal that the IMF is heavier when the pressure of the star-forming gas is higher (e.g. Barber et al. 2018 and references therein), one might expect that at lower $z$ stars form with IMF lighter than that of stars formed at higher redshift (because the pressure of the gas form which stars form tends to decrease with cosmic time; Barber et al. 2018). However, as far as we know, it is not excluded, either theoretically or observationally, that at lower $z$ stars can form with heavier IMF.

4.5.3 Comparison with observations and with previous models

The theoretical predictions on the evolution of the $\alpha_e$-$\sigma_e$ relation can be tested with measurements of $\alpha_e$ and $\sigma_e$ at different redshifts. However, so far such measurements are relatively rare and it is difficult to draw robust conclusions. On the one hand, Sonnenfeld et al. (2015) find that in an observed sample of lens ETGs, $\alpha_e$ tends to decrease with increasing redshift, at fixed $\sigma_e$, out to $z \approx 0.8$. On the other hand, Martin-Navarro et al. (2015b) find that massive ETGs at $z \approx 0.75$ have, at given $\sigma_e$, IMF similar to that of lower-$z$ galaxies (or slightly heavier; see Sonnenfeld et al. 2017). Recently, Mendel et al. (2020) measured $\alpha_e$ and $\sigma_e$ for a sample of quiescent galaxies at $1.4 < z < 2.1$, finding a steeper $\alpha_e$-$\sigma_e$ relation, which overlaps with the $z \approx 0$ relation at the high-$\sigma_e$ end. The trend found by Sonnenfeld et al. (2015) and Mendel et al. (2020) (higher-$z$ galaxies tend to have lower $\alpha_e$ at given $\sigma_e$) appears in tension with the compact-satellite evolutionary model depicted in Fig. 9 and more consistent with the hypothesis of diffuse satellites. It should be noted, though, that the measurements of both Sonnenfeld et al. (2015) and Mendel et al. (2020) are relying on a set of assumptions, most notably that of a spatially constant stellar mass-to-light ratio at all redshifts. This assumption can have a big impact on their estimates of the IMF (see e.g. Sonnenfeld et al. 2018 and Bernardi et al. 2018) and, consequently, on their measured trend with redshift.

The theoretical model of Sonnenfeld et al. (2017), who found a negligible evolution of the $\alpha_e$-$\sigma_e$ relation (i.e. $\alpha_e$ at given $\sigma_e$ independent of redshift), lies in between the compact-satellite and the
diffuse-satellite scenarios depicted in Fig. 9. In our simulations both the effective velocity dispersion and the effective IMF mismatch parameter of the remnants are computed self-consistently accounting for the internal kinematics, structure and $\alpha_{IMF}$ distribution of the N-body systems. In their statistical approach, Sonnenfeld et al. (2017) assume that $\sigma_e$ is proportional to the virial velocity dispersion and that $\alpha_e$ of the remnant is the weighted mean of $\alpha_e$ of the progenitor galaxies. When this weighted mean is adopted, $\alpha_e$ of the remnant is overestimated compared to the case of compact satellites, in which most of the variation of $\alpha_{IMF}$ occurs in the center, so, in this respect, the model of Sonnenfeld et al. (2017) is closer to the diffuse-satellite scenario. Qualitatively, our compact-satellite scenario predicts an evolution of the $\alpha_e$-$\sigma_e$ relation broadly consistent with the cosmological model ‘LoM’ of Barber et al. (2019b) and with that of Blanchard et al. (2017), which both predict higher $\alpha_e$ at higher redshift, for given $\sigma_e$.

5 CONCLUSIONS
We have studied the effect of dissipationless (dry) mergers on the distribution of the IMF mismatch parameter $\alpha_{IMF}$ in ETGs using the results of dissipationless binary major and minor merging simulations. Our main conclusions are the following:

- Dissipationless mergers tend to make the $\alpha_{IMF}$ profiles of ETGs shallower, and in particular to produce flat central ($R \lesssim 0.3 R_e$) $\alpha_{IMF}$ distributions.
- Dissipationless mergers do not alter significantly the shape of the spatially resolved distributions in the $\alpha_{IMF}$-$\sigma_e$ space: when the progenitor galaxies have realistic distributions in this space, this is true also for the merger remnants.
- Individual galaxies undergoing dry mergers move, in the space of integrated quantities $\alpha_e$-$\sigma_e$, by decreasing their $\alpha_e$, due to the erosion of $\alpha_{IMF}$ gradients and mixing with stellar populations with lighter IMF, while their $\sigma_e$ can either decrease or increase, depending on the merging orbital parameters and mass ratio. $\sigma_e$ tends to decrease in cosmologically motivated merging histories.
- The dry-merger driven evolution of the $\alpha_e$-$\sigma_e$ relation of ETGs depends on the nature of the accreted satellites: galaxies of given $\sigma_e$ are expected to have higher $\alpha_e$ at higher redshift if the satellites are compact, but the trend can be opposite if the satellites are sufficiently diffuse.

The effects of dry mergers on the $\alpha_{IMF}$ distribution and on the $\alpha_e$-$\sigma_e$ predicted by our model are not dramatic and are thus broadly consistent with the currently available observational constraints, which are however limited and somewhat controversial. Some observational estimates of the evolution of the $\alpha_e$-$\sigma_e$ relation of ETGs (Sonnenfeld et al. 2015; Mendel et al. 2020) indicate that $\alpha_e$ at given $\sigma_e$ tends to be lower than at higher $z$. This is in tension with the predictions of dry-merger simulations in which the satellites are compact, and suggest that accretion of diffuse satellites might be invoked to reconcile a dry-merger driven evolution with observational data. Additional measurements of the properties of the IMF of ETGs beyond the present-day Universe are necessary to further test the two-phase formation model of massive ETGs, in which essentially dissipationless mergers have an important role at $z \lesssim 2$. A very promising possibility is to estimate $\alpha_e$ of lens ETGs by combining constraints on the total mass from gravitational lensing with spatially resolved kinematics (see Treu et al. 2010), which will be feasible over a significant redshift range with forthcoming telescopes and instruments (e.g. Shajib et al. 2018).

APPENDIX A: VARYING THE $\alpha_{\text{IMF}}$ PROFILES OF THE PROGENITOR GALAXIES

In Section 4 we have described how we assign $\alpha_{\text{IMF}}$ to the stellar particles of the simulation by choosing the values of the dimensionless parameters $A_{\text{IMF}}$, $B_{\text{IMF}}$ and $C_{\text{IMF}}$. Here we illustrate the effect of changing the values of these parameters. We focus on equal-mass mergers simulations and we fix in all cases $C_{\text{IMF}} = 1$ so that the two progenitor galaxies are identical, not only structurally and kinematically, but also in terms of distribution of IMF. In particular, we describe here the properties of models D1h and D1h_bis (upper panel), and off-axis merger models D1o and D1o_bis (lower panel). Models D1h_bis and D1o_bis are based on the same simulations as models D1h and D1o, respectively, but in post-processing different values of $A_{\text{IMF}}$ and $B_{\text{IMF}}$ are assumed. The progenitor galaxies (hexagons) and the remnants (squares and circles) of models D1h and D1o ($A_{\text{IMF}} = 2$, $B_{\text{IMF}} = 0$) are represented by grey symbols, while those of models D1h_bis and D1o_bis ($A_{\text{IMF}} = 0.5$, $B_{\text{IMF}} = 1$) by green symbols.

Figure A1. Same as lower panel of Fig. 1, but for the equal-mass head-on merger models D1h and D1h_bis (upper panel), and off-axis merger models D1o and D1o_bis (lower panel). Models D1h_bis and D1o_bis are based on the same simulations as models D1h and D1o, respectively, but in post-processing different values of $A_{\text{IMF}}$ and $B_{\text{IMF}}$ are assumed. The progenitor galaxies (hexagons) and the remnants (squares and circles) of models D1h and D1o ($A_{\text{IMF}} = 2$, $B_{\text{IMF}} = 0$) are represented by grey symbols, while those of models D1h_bis and D1o_bis ($A_{\text{IMF}} = 0.5$, $B_{\text{IMF}} = 1$) by green symbols.

mertical, but also in terms of distribution of $\alpha_{\text{IMF}}$. In particular, we describe here the properties of models D1h_bis and D1o_bis, comparing them with those of models D1h and D1o. Models D1h_bis and D1o_bis are based on the same simulations as models D1h and D1o, respectively, but in post-processing different values of $A_{\text{IMF}}$ and $B_{\text{IMF}}$ are assumed (see Table 1). The progenitor galaxies of models D1h_bis and D1o_bis have weaker dependence of $\alpha_{\text{IMF}}$ on the integral of motion $Q$ ($A_{\text{IMF}} = 0.5$ and $B_{\text{IMF}} = 1$) and thus shallower gradients of $\alpha_{\text{IMF}}$ (Fig. A1) than those of models D1h and D1o, which have $A_{\text{IMF}} = 2$ and $B_{\text{IMF}} = 0$. In this sense, models D1h_bis and D1o_bis are less realistic than models D1h and D1o, when compared to the $\alpha_{\text{IMF}}$ profiles of their progenitor galaxies, the remnants of models D1h_bis and D1o_bis have normalized $\alpha_{\text{IMF}}$ profiles almost indistinguishable from those of the progenitors (Fig. A1). Fig. A2 shows that both the progen-
Here we consider the merger-driven evolution in the in the $\sigma_{\text{los}}$-$\sigma_{e,\text{main}}$ space of the remnants and the progenitors differ essentially only for variations in $\sigma_{\text{los}}$. Consistently, also the merger-driven evolution in the $\sigma_{\text{los}}$-$\sigma_{e,\text{main}}$ space is weaker for models D1h_bis and D1o_bis than for models D1h and D1o (Fig. A3). Models D1h_bis and D1o_bis are presented here only for the purpose of illustrating the effect of changing the values of $A_{\text{MB}}$ and $B_{\text{MB}}$, but, for the aforementioned reasons, should not be considered as representative of real ETGs as models D1h and D1o.

**APPENDIX B: MERGERS BETWEEN NON-HOMOLOGOUS GALAXIES**

In Section 4, we have presented results of simulations (set D) in which the main and satellite galaxies are homologous stellar systems. Of course, this simplification is not fully justified, especially in the case of minor mergers, because we expect that galaxies of different stellar mass differ in their structural properties, for instance in the distribution and amount of dark matter, relative to the baryonic matter (Wechsler & Tinker 2018). Here we consider $\xi_* = 0.2$ simulations of sets D3 (0.2D3h and 0.2D3o) and D4 (0.2D4h and 0.2D4o), in which the structure of the satellite progenitor galaxy differs significantly from that of the main galaxy, and we compare them with the corresponding simulations of set D (0.2Dh and 0.2Do). The values of the parameters of these sets of simulations is reported in Table 1 and are chosen to span the range of values expected for real galaxies, with dark-to-luminous mass ratios ranging from 35 to 70 (see Sonnenfeld et al. 2014). Due to the non-homology, also the $\sigma_{\text{los}}$ profiles of the satellite progenitor galaxies are not identical in simulations of sets D, D3 and D4, but the $\sigma_{\text{los}}$ profiles of the remnants are almost indistinguishable out to $\approx 3R_e$. The values of $C_{\text{MB}}$ are such that the satellite and main galaxies lie on the same $\alpha_\text{los}$-$\sigma_e$ power-law relation (equation 2), and are thus different for the three sets of $\xi_*$ = 0.2 simulations, but the $\sigma_{\text{los}}$ profiles of the remnants are similar in the three cases. Here we show only the distributions of $\sigma_{\text{los}}$ as a function of $\sigma_{\text{los}}$ (Fig. B1), which for the remnants of simulations of sets D3 and D4 are very similar to those of the corresponding simulations of set D. We thus conclude that our results do not depend significantly on the amount and distribution of dark-matter in the satellite galaxy.
Figure B1. Same as bottom panel of Fig. 6, but for the $\xi_* = 0.2$ head-on merger simulations 0.2Dh (set D; grey), 0.2D3h (set D3; red) and 0.2D4h (set D4; green), and off-axis merger simulations 0.2Do (set D; grey), 0.2D3o (set D3; red) and 0.2D4o (set D4; green).
